In many bacteria, the *glnA* gene is regulated by the availability of ammonium through the global N-control circuits. Additionally, in *E. coli*, the GS activity is regulated by a tight bicyclic regulatory cascade (Fig. 4), which shares components of N-regulation. In this circuit, each of the 12 GS subunits can be modified through adenylation/deadenylation by GlnE, a bifunctional adenylyl transferase/removing enzyme (ATase). Adenylylation reduces the catalytic activity of GS, and although high glutamine levels do not directly inhibit GS activity, they determine ATase-mediated adenylylation. Conversely, high levels of 2-oxoglutarate stimulate deadenylation. In turn, ATase activity is under control of the P_{II}/uridylyl transferase (UTase, the *glnD* gene product) cascade: GlnB (and to a lower extent GlnK) stimulates adenylylation and GlnB-UMP (GlnK-UMP) stimulates deadenylation. ATase appears to preferentially sense two forms of the P_{II} protein: trimers bound to one 2-oxoglutarate stimulate adenylylation, while fully uridylylated and 2-oxoglutarate saturated trimers stimulate deadenylation.

Assimilation of Organic Sources of Nitrogen

A large diversity of nitrogenous organic compounds can be used as sources of nitrogen in the bacterial world. Relatively simple compounds that can be used by different bacteria include urea, some amino acids, amino sugars and simple amine-containing compounds such as methylamine, ethanolamine or some polyamines. Utilization of amino acids sometimes implies previous degradation of peptides that should be considered the actual nitrogen source. Other complex compounds such as heterocyclic

Fig. 4 Regulation of glutamine synthetase in *Escherichia coli*. Adenylation of GS reduces its activity, and each of the twelve subunits can be independently adenylylated/deadenylylated by adenylyl transferase (ATase). High levels of glutamine favor adenylation, while low levels result in deadenylation. In addition, ATase activity is modulated by the P_{II} proteins, GlnB and GlnK. These proteins can bind 2-oxoglutarate (2OG) and be modified by uridylation. Both uridylation and deuridylation are catalyzed by UTase. High levels of glutamine favor deuridylation, while low levels result in uridylation. Two forms of the P_{II} proteins are shown. When completely deuridylylated and bound to one 2OG, P_{II} proteins stimulate the adenylyl transferase activity of ATase. When completely uridylylated and bound to three 2OG, P_{II} proteins stimulate the adenylyl removing activity of ATase. GlnK has a much lower effect on ATase, and this is denoted by dashed lines. This cascade system responds, in a highly sensitive manner, to variations in the intracellular N status, since it senses the levels of both glutamine and its C precursor (2OG). Yellow diamonds, 2-oxoglutarate (2OG); red diamonds, UMP; orange diamonds, AMP.

nitrogenous compounds including, e.g., nitrogenous bases (pyrimidines and purines) or xenobiotics such as atrazine can also be used by some bacteria. The utilization of an organic nitrogenous compound as a nitrogen source requires the uptake of the substrate into the bacterial cell. Then, specific metabolic route(s) catabolize the substrate to produce ammonium that is incorporated into amino acids. In many cases, the bacteria completely mineralize the substrate releasing ammonium. Some amino acids, on the other hand, are catabolized producing glutamate, which is the major distributor of nitrogen in metabolism; however, degradation of the amino acid should also produce ammonium to be used by GS to synthesize glutamine (Fig. 2).

The myriad of bacterial pathways involved in the utilization of organic sources of nitrogen cannot be covered here. We will therefore outline examples of the pathways of utilization of a few substrates that can enlighten the reader about the variety of catabolic pathways displayed in the bacterial world.

Urea

Urea ($\text{CO}[\text{NH}_2]_2$) is a simple organic compound present in both ocean and fresh waters as well as in the soil (in part because of its use as fertilizer), frequently at micromolar concentrations or below, and it can be assimilated by bacteria belonging to different phylogenetic groups. Although urea at relatively high (millimolar) concentrations can permeate biological membranes permitting at least slow growth, it can also be incorporated into many bacteria by an active transporter. Once inside the cell, urea is degraded by urease to produce CO_2 and ammonium, which is incorporated into organic material (Fig. 2).

Genes and proteins

Active uptake of urea appears essential to assimilate this compound when found below micromolar concentration. Bacterial urea uptake is mediated by an ABC-type transporter that was first identified in cyanobacteria. ABC uptake transporters typically comprise one periplasmic solute-binding protein, two integral membrane (transmembrane or permease) proteins/domains and two nucleotide-binding proteins/domains that hydrolyze ATP in the cytoplasm. The urea transporter is encoded by five genes that form an operon with a typical structure for ABC transporter-encoding operons, including (5' to 3') the genes for the periplasmic substrate-binding protein (UrtA), the transmembrane proteins (UrtB, UrtC), and the nucleotide-binding proteins (UrtD, UrtE) (Fig. 5). This transporter shows a high affinity for urea (K_s about 0.1 μM in the cyanobacterium *Anabaena* sp. PCC 7120), keeping the concentration of urea in the cytoplasm to a level usable by urease.

Fig. 5 The urea assimilation system. Urea is taken up into the cells with high affinity by an ABC transporter. These transporters are constituted by a periplasmic substrate-binding protein (yellow), two transmembrane proteins (pink) and two nucleotide-binding proteins (green) that hydrolyze ATP in the cytoplasm. Urea is concentrated inside the cell to a level that can be used by the urease complex, which has lower affinity for urea than the transporter. Urease is made up of three different subunits (genes depicted in brown) and bears a nickel-containing active center that is the product of a maturation process carried out by the products of urease-specific maturation genes (genes depicted in blue). All the genes required for urea assimilation are frequently clustered together in bacterial genomes, as exemplified by the urea assimilation gene cluster of the unicellular cyanobacterium *Prochlorococcus marinus* strain MIT 9113.

Urease (urea amidohydrolase) catalyzes the hydrolysis of urea to produce ammonia and carbamate, which spontaneously decomposes into another molecule of ammonia and carbonic acid. Urease is a trimer of a complex formed itself by three subunits encoded by the *ureA*, *ureB* and *ureC* genes. Each UreABC complex bears, located in UreC, a catalytic site that contains two nickel ions bridged by a carbamylated lysine and coordinated by histidine and aspartate residues. Synthesis of active urease is a complex GTP-dependent process that requires the products of accessory genes, *ureD*, *ureE*, *ureF* and *ureG*, which have a role in metallocenter assembly (Fig. 5).

The urease structural and maturation genes are generally clustered together in bacterial genomes and, interestingly, they are also frequently clustered with the urea ABC transporter-encoding genes, which may be found in the same or opposite orientation (Fig. 5). This arrangement may suggest that all these genes are subjected to concerted regulation, but also (or alternatively) that they have been received as a package by horizontal gene transfer in the bacterium where the cluster is found.

Regulation

The *urt* genes encoding the urease transporter are subjected to N control, so that they are expressed at high levels only under nitrogen deficiency. This is the case in, e.g., the cyanobacterium *Anabaena* sp. PCC 7120, where the *urt* operon is transcribed from an NtcA-dependent promoter, and *Mycobacterium smegmatis*, where the *urt* genes are under the control of the response regulator GlnR. In contrast, urease-encoding genes are expressed constitutively in some bacteria but regulated in others. Amongst the latter, the *Klebsiella pneumoniae* *ure* genes are transcribed from two promoters, one of which is strictly dependent on the nitrogen assimilation regulator Nac, which is a LysR-type factor that activates σ^{70} -dependent transcription in the absence of any effector (i.e., Nac is not regulated at the protein activity level). Instead, the expression of the *nac* gene is dependent on the Ntr system (see Section “Nitrogen Control”, the *E. coli* cascade system).

In conclusion, the urea transporter appears to have an important role in urea scavenging, permitting the proliferation of urea-assimilating bacteria in natural habitats where urea may be found at low concentrations. A urease regulated in a similar way as the transporter would contribute to this function. On the other hand, in some bacteria urease participates in specific metabolic pathways (e.g., in arginine catabolism; see Fig. 2) that require constitutive expression or expression regulated independently of nitrogen control. Additionally, urease has an important role in virulence and/or adaptation to acidic environments in bacteria such as *Streptococcus* sp., *Proteus* sp. and *Helicobacter* sp., but this topic is outside the scope of this article.

Aspartate, Asparagine, Glutamate and Glutamine

These amino acids can be used as sources of nitrogen by many bacteria. The utilization of glutamate and glutamine is straightforward. Specific glutamate uptake systems of different transporter families are found in bacteria, including secondary H^+ - or Na^+ -dependent transporters such as the Na^+ -dependent GltS of *E. coli*, or ABC transporters such as GluABCD from *Corynebacterium glutamicum*. There are also transporters for glutamate and related compounds such as the H^+ -dependent symporters for aspartate or glutamate, TRAP (Tripartite ATP-independent periplasmic) transporters for dicarboxylates, or ABC transporters for aspartate/glutamate/asparagine/glutamine in numerous bacteria. Once inside the cells, glutamate can be used

directly in metabolism or deaminated by glutamate dehydrogenase, releasing ammonium. Regarding glutamine, it can be taken up by shared transporters and also by specific transporters such as the ABC transporter GlnHPQ of enterobacteria. Glutamine can be deaminated by specific glutaminases (glutamine amidohydrolases) producing glutamate and ammonium, but it can also be used to distribute nitrogen directly in metabolism through amidotransferases that bear glutaminase domains. The utilization of glutamine is however subjected to some nuances in organisms, such as the enterobacteria, in which glutamine is itself an indicator of the carbon-to-nitrogen balance of the cell. Hence, although abundant glutamine should be perceived as nitrogen excess (see Section "Nitrogen Control", the *E. coli* cascade system), growth of *E. coli* on glutamine as a nitrogen source induces the Ntr response.

Aspartate can be incorporated into bacterial cells by secondary transporters of the Dicarboxylate/Amino Acid:Cation (Na^+ or H^+) Symporter (DAACS) Family such as GltP (in *E. coli*) or GltT (in *B. subtilis*), or by ABC transporters such as GltIJKL (in *E. coli*). Once inside the cell, aspartate can be subjected to transamination to 2-oxoglutarate catalyzed by aspartate aminotransferase to produce oxaloacetate and glutamate, or to deamination catalyzed by aspartase (aspartate-ammonia lyase) to produce fumarate and ammonium. Many bacteria, including phylogenetically distant organisms such as *E. coli* and *B. subtilis*, can metabolize aspartate with these two enzymes making nitrogen available for anabolism in two forms: glutamate and ammonium (Fig. 2).

Asparagine can provide nitrogen directly in the form of ammonium and, further, through aspartate catabolism. Asparaginases are hydrolytic enzymes that produce aspartate and ammonium. *B. subtilis* expresses two periplasmic asparaginases, one, termed AnsZ, that is subjected to nitrogen control and another, termed AnsA, that is induced by asparagine or aspartate. The *ansA* gene forms an operon with *ansB* that encodes an aspartase. Hence, in the presence of an inducer, *B. subtilis* can obtain two ammonium molecules from one asparagine molecule with the concurrence of a periplasmic hydrolytic enzyme, a permease, and a cytoplasmic deaminating enzyme (Fig. 2). This pathway also involves the ammonium translocator AmtB (formerly known as NrgA in *B. subtilis*) to incorporate into the cytoplasm the ammonium produced in the periplasm.

The enterobacteria express two asparaginases: a cytoplasmic low-affinity enzyme (the *ansA* gene product) and a periplasmic high-affinity enzyme (the *ansB* gene product), which are not homologous. This permits metabolism of both asparagine incorporated into the cell and extracellular asparagine. Asparagine transporters are known in bacteria, including e.g., *E. coli* AnsP, a member of the Amino Acid-Polyamine-Organocation (APC) Superfamily of secondary transporters, and *Rhodobacter capsulatus* BztABCD, an ABC transporter for Glu/Gln/Asp/Asn. Aspartate produced by cytoplasmic asparaginase can be metabolized as described above for that taken up from the extracellular medium.

Regulation of expression of the genes encoding the elements for the different routes for asparagine and aspartate degradation can determine preferential utilization of these amino acids under certain conditions in particular bacteria. In *E. coli*, fumarate is a respiratory substrate, and under anaerobic conditions aspartate-fumarate antiporters (DcuA, DcuB) are induced that translocate fumarate to the periplasm, where it is used in respiration. Interestingly, under these conditions the periplasmic asparaginase is also induced, and asparagine is preferentially hydrolyzed in the periplasmic space, allowing the operation of the aspartate-fumarate antiporter. In contrast, in *Klebsiella* the periplasmic asparaginase is subjected to N control, which is consistent with a specific role in nitrogen nutrition. The utilization of asparagine and aspartate thus illustrates the plasticity of bacteria, which can use different types of transporters, including secondary transporters and high-affinity ABC transporters, and different enzyme localization strategies (periplasmic, cytoplasmic) to integrate assimilatory pathways and other important physiological processes of the bacterium such as respiration.

Arginine

Arginine is the amino acid richest in nitrogen, since it contains four N atoms within a six C atom skeleton. Hence, it is not surprising that arginine can be used as a source of nitrogen by many bacteria, which is reflected in the high number of different arginine catabolism pathways that can be found in the bacterial world. Whereas the nitrogen substrates discussed in this article generally traverse the outer membrane of Gram-negative bacteria through non-specific or low-specificity porins, a porin specific for basic amino acids, OprD, is involved in arginine utilization by *Pseudomonas aeruginosa*. Arginine can be taken up into bacterial cells by arginine-specific or basic amino acid ABC transporters, of which the HisJ/ArgT-HisMQP system of *Salmonella typhimurium* – which is involved in the transport of His, Lys, Arg and ornithine – is a well-known example, or by arginine/ornithine antiporters of the APC superfamily. At least seven arginine catabolism pathways are found in bacteria, but only three of them utilize efficiently the four N atoms contained in arginine:

- (1) In the arginase pathway, well characterized in *Bacillus*, in which arginine is the second preferred nitrogen source (only after glutamine), urea is first removed from arginine by arginase (arginine ureohydrolase) with the concomitant production of ornithine (Fig. 2). Urea is then degraded by urease producing two ammonium molecules and CO_2 , and ornithine is further catabolized to glutamate via glutamate semialdehyde/ Δ^1 -pyrolysine-5-carboxylate, which involves a transamination to 2-oxoglutarate producing a second glutamate molecule. Hence, in this pathway, the four N atoms of arginine are conserved in two ammonium molecules and two glutamate molecules.
- (2) In an alternative arginase pathway that has been well characterized in *Agrobacterium*, ornithine cyclodeaminase releases ammonium producing proline that is further catabolized to glutamate by the bifunctional enzyme proline oxidase, PutA. In this pathway, three ammonium molecules and one glutamate molecule are produced per arginine consumed.

- (3) In a variation of arginine catabolism found in some bacteria including the enterobacteria and Pseudomonads, arginine is activated by addition of succinyl-coenzyme A to produce N²-succinylarginine that follows a pathway similar to that of arginase to finally release succinate and glutamate. However, the second enzyme of this pathway, N²-succinylarginine dihydrolase, releases two ammonium molecules and CO₂ instead of urea as arginase does. Hence, the arginine succinyltransferase pathway directly produces two ammonium molecules and two glutamate molecules per arginine consumed. Other pathways make use of the arginine molecule with different purposes. Only the two most relevant of these pathways will be described here:
- (4) In the arginine deiminase pathway, present in many phylogenetically different bacteria, arginine is first deaminated producing ammonium and citrulline, which is then used by catabolic ornithine carbamoyltransferase to produce ornithine and carbamoyl phosphate. Whereas carbamoyl phosphate is used by carbamate kinase to produce ATP, ornithine is excreted in exchange for arginine by an arginine/ornithine antiporter. Hence, this pathway only produces one ammonium molecule per arginine utilized, but additionally produces ATP, which makes it useful as an energy-producing pathway under anaerobic conditions.
- (5) Arginine decarboxylase produces agmatine that is further catabolized by agmatine ureohydrolase (agmatinase, which is homologous to arginase) releasing putrescine and urea, which can be hydrolyzed by urease producing two ammonium molecules and CO₂. Putrescine is a polyamine and is itself a source for synthesis of other polyamines, including spermidine. Hence, although the arginine decarboxylase pathway releases N in the form of urea (and further on ammonium), its main role appears to be the production of polyamines that are essential in many organisms.

The arginine utilization pathways outlined here illustrate the efficient use of arginine as a nitrogen source, but also its use for other metabolic purposes such as energy-conservation and polyamine biosynthesis. Utilization of arginine as a nitrogen source is tightly regulated in some bacteria such as the enterobacteria, in which expression of the *ast* operon encoding enzymes of the arginine succinyltransferase pathway requires nitrogen limitation and is mediated by the Ntr regulatory system. Interestingly, however, the widely-distributed repressor of arginine biosynthesis, ArgR, a transcriptional regulator of the winged helix-turn-helix (wHTH) family of DNA binding proteins that binds DNA in the presence of arginine, is also involved in expression of the *ast* operon in the presence of arginine. ArgR-arginine binds to the *ast* promoter likely facilitating the action of NtrC. The other physiological functions of arginine catabolism involve specific regulations too. Thus, for instance, expression under anoxic conditions of the *arc* operon encoding the proteins of the arginine deiminase pathway in *Pseudomonas aeruginosa* is mediated by the global regulator of anaerobic metabolism, ANR (a transcriptional regulator of the CRP/FNR family).

Histidine

Histidine is rich in nitrogen (three N atoms in a six C atom skeleton) and can be assimilated by many, although not all bacteria. The histidine assimilation pathway is relatively complex but well conserved among bacteria. It involves histidine uptake and further degradation in four or five successive enzymatic steps, producing one glutamate and one or two ammonium molecules, respectively, per histidine molecule consumed. Because the imidazole side chain of histidine has a pK_a of 6.0, at a neutral pH histidine can be taken up through both neutral and basic amino acid ABC uptake transporters. Thus, the ABC basic amino acid transporter HisJ/ArgT-HisMQP of *Salmonella typhimurium* is involved in histidine uptake. Additionally, there are histidine-specific transporters such as the HutT permease of the Pseudomonads, a secondary transporter of the APC family.

Histidine is deaminated by histidase (the *hutH* gene product) producing ammonia and urocanate, which is subjected to two successive hydration steps mediated by urocanase (the *hutU* gene product) and imidazolone propionate hydrolase (the *hutI* gene product) forming imidazole propionate and formimino glutamate, respectively. In some bacteria (e.g., those of the genera *Bacillus* and *Klebsiella*), formimino glutamate is hydrolyzed by formimino glutamate hydrolase (the *hutG* gene product) releasing glutamate and formamide, which is not further catabolized, being instead excreted. In these bacteria, therefore, the pathway renders one glutamate molecule and one ammonium molecule per histidine consumed (Fig. 2). In other bacteria (e.g., those of the genera *Pseudomonas* and *Streptomyces*), formimino glutamate deiminase (the *hutF* gene product) produces ammonium and formyl glutamate, which is hydrolyzed by formylglutamate hydrolase (the product of a *hutG* gene that is not homologous to that of *Bacillus* or *Klebsiella*) releasing formate and glutamate. Hence, in these bacteria two molecules of ammonium and one molecule of glutamate are obtained per histidine consumed (Fig. 2), which represents an optimal efficiency in the utilization of histidine as a nitrogen source.

The *hut* genes encoding histidine catabolism enzymes and a transporter-encoding gene, *hutT*, are frequently clustered together constituting one or several transcriptional units. A gene, *hutC*, encoding a transcriptional repressor is also frequently found in the *hut* gene cluster. Because the biosynthesis of histidine is energetically expensive, the expression of the catabolic *hut* genes is subjected to tight regulation to avoid a futile cycle. Thus, the *hut* genes are only expressed if excess histidine is available and a shortage of nitrogen or carbon is perceived in the cells. Urocanate (the first catabolic product) is an inducer blocking the HutC repressor activity, thus ensuring that the *hut* genes are expressed only if histidine is abundant. An important variation in the mechanism of induction is found in *Bacillus*, where histidine-promoted anti-termination mediated by a protein termed HutP is in operation. Additionally, *hut* genes are subjected to catabolite repression and to N control. In enterobacteria, catabolite repression implies cAMP-CRP-mediated activation of expression of the *hut* genes, and their expression under nitrogen deficiency requires the Nac transcription factor. C- and N-regulation of *hut* genes in other bacteria such as those of the genera *Pseudomonas* or *Streptomyces* is carried out by their corresponding global regulatory systems.

Atrazine and Cyanuric Acid

Atrazine is very rich in nitrogen (five N atoms in an eight C atom skeleton), and an atrazine-mineralization pathway is encoded in plasmids found in some Pseudomonads, which make such organisms capable of using this xenobiotic as a nitrogen source. Cyanuric acid, an intermediate in the atrazine degradation pathway, can also be used as nitrogen source in these bacteria. Atrazine mineralization frequently occurs via a hydrolytic pathway that proceeds through the sequential elimination of the chlorine, ethylamino and isopropylamino substituents, to yield cyanuric acid that is cleaved and mineralized to CO₂ and ammonia (Fig. 2). Thus, mineralization of atrazine renders one ethylammonium and one isopropylammonium molecule, on one hand, and three ammonium molecules that can be directly incorporated into carbon skeletons, on the other. Not surprisingly, the capability to use atrazine is only expressed under nitrogen deficiency, but this is based in regulation of only part of the atrazine degradation pathway. Whereas the genes encoding the enzymes that catalyze the first three steps in the pathway (*atzA*, *atzB*, *atzC*) are scattered in the atrazine-catabolism plasmid and appear to be constitutive, the genes encoding the enzymes that catalyze the last three steps of the pathway (those involved in degradation of cyanuric acid) constitute an operon (*atzDEF*) whose expression is tightly regulated. The *atzDEF* promoter is a standard σ^{70} -dependent promoter that is activated by AtzR, a LysR-type transcriptional regulator that is encoded just upstream, divergently from the operon. The *atzR* gene is expressed from a σ^{54} -dependent promoter whose activation requires the general Ntr system of the bacterium, thus linking the capability to mineralize atrazine to nitrogen deficiency. The AtzR protein additionally requires cyanuric acid as a co-activator, and its activity is further enhanced by uridylylated GlnK. In addition to the only partial regulation of the atrazine degradation pathway, it is of interest that whereas the plasmid bearing the genes for atrazine/cyanuric acid degradation also has genes encoding an ABC transporter for cyanuric acid, the presence of a transporter for atrazine is unclear. Hence, atrazine is a nitrogen source whose utilization has likely involved the integration of genes specific for its degradation down to cyanuric acid with a pre-existing pathway for the utilization of this compound. Thus, degradation of atrazine and cyanuric acid exemplifies the adaptability of bacteria that have evolved to use xenobiotics as nitrogen nutrients.

The Assimilation of Nitrate

Nitrates are present at low concentrations (micromolar or below) in natural habitats including the oceans. However, nitrates are relatively abundant in local areas, especially those that hold extensive agricultural activity, because the use of excessive fertilization often leads to nitrate leakage into the environment. Nitrate is an excellent nitrogen source for many bacteria, fungi, algae and plants, and its assimilation involves entrance into the cell by an active transporter and its intracellular reduction to ammonium by two sequential reductive reactions, with ammonium being finally incorporated into organic material (Fig. 2).

Nitrate Uptake

Two types of active transport systems for nitrate, which can also accept nitrite, have been described in bacteria: ABC-type transporters and MFS permeases. Whereas the nitrate/nitrite transporters described in several bacteria (such as *K. oxytoca*) conform to the basic structure of ABC transporters, in cyanobacteria the Nrt transport system presents some peculiarities. First, the binding protein, NrtA, is anchored to the periplasmic side of the cytoplasmic membrane by post-transcriptional processing (including lipidation) by signal peptidase II and, second, the ATPase domain is made of two different subunits: NrtD, a standard ATPase subunit, and NrtC, a long protein with an N-terminal part similar to NrtD and a C-terminal part homologous to NrtA. The permease domain of Nrt is made of two NrtB subunits, each providing 5-transmembrane helices.

Major facilitator superfamily (MFS) permeases are made of dimers of a single gene product that normally contains 12 transmembrane segments and couple substrate transport or exchange through the cytoplasmic membrane to the dissipation of an electrochemical gradient. The *Bacillus subtilis* or *Paracoccus denitrificans* NasA, the *Synechococcus* sp. PCC 7002 NrtP and the *Trichodesmium* sp. WH9601 NapA belong to this family of transporters and couple nitrate/nitrite transport to a H⁺ or Na⁺ gradient.

Nitrate Reduction

Intracellular nitrate is first reduced to nitrite in a 2e⁻-transfer reaction catalyzed by nitrate reductase, and the resulting nitrite is then reduced to ammonium in a 6e⁻-transfer reaction catalyzed by nitrite reductase. In spite of this general scheme, the reductases largely diverge in structure and electron transfer paths depending on the organism. In cyanobacteria, which are characterized by a photoautotrophic mode of life relying on oxygenic photosynthesis, both nitrate reductase and nitrite reductase utilize photosynthetically reduced ferredoxin or flavodoxin as the electron donor. In most heterotrophic bacteria, and some anoxygenic phototrophs such as *Rhodobacter capsulatus*, both reductases accept electrons from reduced pyridine nucleotides (NADH), although some exceptions are found. For example, the nitrate reductase from *Azotobacter vinelandii* uses reduced flavodoxin, and the nitrate reductase from the chemolithoautotroph *Hydrogenobacter thermophilus* and the nitrate and nitrite reductases from the archaeon *Haloferax mediterranei* utilize reduced ferredoxin as electron donor.

Fig. 6 Scheme of the electron transfer pathways in cyanobacterial nitrate reductase (NarB) and nitrite reductase (NirA). The cyanobacterial nitrate reduction system is special in that both reductases use ferredoxin as an electron donor, but at the same time it is illustrative of the nitrate reduction process. Ferredoxin donates electrons (one at a time) to an iron-sulfur cluster in NarB, from which they follow a typical pathway to reduce nitrate to nitrite in a 2- e^- reduction reaction catalyzed in the Mo-bis-molybdopterin-guanine dinucleotide active center. NirA also uses reduced ferredoxin as an electron donor, and here the six electrons required to reduce nitrite to ammonium are transferred (one at a time) through an iron-sulfur center and a siroheme group, in which the reduction of the substrate takes place.

Nitrate reductase

The cyanobacterial nitrate reductase, as of that of *Synechococcus elongatus*, is a monomeric enzyme of ca. 80 kDa, the product of the *narB* gene, containing one [4Fe-4S] cluster, which receives electrons from the external electron donor, and a molybdenum-bis-molybdopterin guanine dinucleotide (Mo-bisMGD) cofactor, which represents the active site for nitrate reduction (Fig. 6). In contrast, NADH-dependent nitrate reductases frequently contain at least one additional reductase subunit, with FAD and sometimes Fe-S clusters, besides the Mo-bisMGD-containing catalytic subunit, which also includes one [4Fe-4S], and sometimes a [2Fe-2S], cluster. In the case of *Klebsiella oxytoca*, nitrate reductase is constituted by a 92-kDa catalytic subunit (NasA -please note, different from *B. subtilis* NasA above), which contains one Mo-bisMGD cofactor, one [4Fe-4S] and one [2Fe-2S] cluster, and a reductase subunit of 43 kDa (NasC), which contains FAD and transfers electrons from NADH to the catalytic subunit. Cyanobacterial Fd-dependent, *H. thermophilus* Fd-dependent and the catalytic subunit of NADH-dependent nitrate reductases, are all homologous proteins.

Nitrite reductase

Although appreciable differences can be found between ferredoxin- and NADH-dependent nitrite reductases, all of them exhibit considerable sequence and structural similarities as well. In particular, all nitrite reductases studied to date include [4Fe-4S] and siroheme groups similar to those of the sulfite reductase hemoprotein from enteric bacteria. The cyanobacterial enzymes are monomers, generally of ca. 55 kDa (NirA), where electrons from ferredoxin are transferred to the [4Fe-4S] cluster and then the siroheme (Fig. 6). Cyanobacterial nitrite reductase has been conserved in the chloroplasts and, hence, is an enzyme of universal relevance in photosynthetic organisms. Bacterial NADH-nitrite reductases may be monomeric, such as that of *K. oxytoca* (NasB), or, as in the case of *B. subtilis*, dimeric and constituted by a large catalytic subunit (NasD) and a small subunit (NasE) with similarity to the carboxy-terminal part of monomeric NasB. Both NasB and NasD include non-covalently bound FAD and two [2Fe-2S] clusters besides [4Fe-4S] and siroheme groups, the two latter as found in cyanobacterial nitrite reductase.

Genetics and Regulation

In cyanobacteria, the genes for the structural components of the nitrate and nitrite assimilation system (nitrate reductase, nitrite reductase and nitrate/nitrite transporter) are frequently clustered together with the order *nirA*-transporter gene(s)-*nirB*, although

some variants of this arrangement can also be found. In the well-studied cyanobacteria *Synechococcus elongatus* and *Anabaena* sp. PCC 7120, these genes constitute an operon that is preceded by additional genes involved in modulation of either the expression of the *nirA* operon or the activity of its encoded elements. Outside of the cyanobacteria, a cluster of nitrate/nitrite assimilation genes has been identified in all the nitrate-assimilating bacteria studied to date, which sometimes also includes regulatory genes and genes for electron donors and synthesis of the nitrite reductase cofactor siroheme or the nitrate reductase cofactor Mo-bisMGD.

Nitrate (and nitrite) assimilation is a costly process due to the energetic requirement for active transport, the high requirement for reducing equivalents and the synthesis of complex reductase cofactors. Thus, in most bacteria, nitrate assimilation is subjected to global N-control circuits (see Section “Nitrogen Control”). In addition, frequently, pathway-specific regulators – often encoded in the nitrate/nitrite assimilation gene cluster – influence the expression of nitrate assimilation genes, in some cases eliciting positive responses to the availability of nitrate or nitrite.

In cyanobacteria, nitrate and nitrite assimilation genes are under global N control exerted by the transcriptional regulator NtcA, and in the case of *Synechococcus*, the activity of the Nrt active transporter for nitrate and nitrite has been shown to be regulated by P_{II} (GlnB), which in cyanobacteria is phosphorylated in response to high 2-oxoglutarate levels. In addition, expression of the *nirA* operon is subjected to pathway-specific regulation by the LysR-type transcription factor NtcB. NtcB exerts a positive effect on the expression of nitrate assimilation genes in the absence of ammonium, which is of high magnitude in the case of *Anabaena* sp. PCC 7120. In this case, NtcB has been shown to bind DNA in the promoter region of the *nirA* operon, close to the binding site for NtcA, and the expression of the *ntcB* gene is itself activated by NtcA.

In many bacteria, responses to the presence of nitrate or nitrite appear to be mediated by transcription anti-termination mechanisms. In *K. oxytoca* and *A. vinelandii*, expression of the *nas* operon is regulated by the general N-control Ntr system. In addition, the factors NasR or NasT, respectively, bind the leader sequence of the *nas* operon mRNA avoiding premature termination, thus promoting transcription completion in the presence of nitrate or nitrite. NasT acts together with NasS, a protein homologous to cyanobacterial NrtA, which may represent a cytoplasmic nitrate/nitrite sensor.

Nitrogen Fixation

In order to enter the biosphere, atmospheric N₂ must be first reduced to a form that can be readily assimilated by organisms, usually ammonium. This reduction is known as nitrogen fixation. Nitrogen fixation is a highly energy-demanding process, given that the triple bond in dinitrogen is very stable and difficult to break down. As a direct result of the inertness of dinitrogen, nitrogen can become a limiting element in ecosystems and, particularly, in agriculture, where fixed nitrogen is the main component of fertilizers.

Biological nitrogen fixation is carried out exclusively by prokaryotes, both bacteria and archaea, collectively known as diazotrophs. Diazotrophy is not limited to any specific group, and it appears to be widely, but haphazardly, distributed throughout different prokaryotic groups. This distribution, together with the high conservation of nitrogen fixation systems (see later in this section) and their extreme oxygen sensitivity, suggest that diazotrophy is a very ancient capability. Ecologically, diazotrophy is also widely distributed. Substantial rates of nitrogen fixation have been observed in terrestrial and aquatic (both freshwater and oceanic) ecosystems, where diazotrophic prokaryotes are often in close, symbiotic associations with eukaryotic organisms, from unicellular algae to fungi, plants and animals.

Nitrogenases

Diazotrophic organisms carry out biological nitrogen fixation under normal conditions of pressure and temperature, compatible with life, through the catalytic action of a complex enzyme, nitrogenase. Although some nitrogenase variants exist, especially regarding the complement of transition metals at their active center, the available information on their structure and organization, as well as on their assembly and biochemistry, denotes a striking conservation of nitrogenases among diazotrophs.

Nitrogenases catalyze the reduction of dinitrogen to ammonia at the expense of ATP, protons and reducing power, according to the equation:

where ammonia is in the protonated ammonium form in solution.

Two striking characteristics of this equation are its high energetic cost, in terms of ATP and reducing power, and the stoichiometric synthesis of one molecule of hydrogen gas per molecule of dinitrogen reduced. The latter is a source of energy inefficiency in the reaction, since 2 e[−] and 4 MgATP are used to make H₂ that can be lost as gas. This is an unavoidable outcome of the complex enzymatic mechanism required to reduce dinitrogen, whereby electrons must be pumped in rapid succession onto a dinitrogen molecule immobilized at the active center that undergoes stepwise reductions through short-lived, unstable intermediates. Nonetheless, many diazotrophs express hydrogenases that can oxidize the hydrogen produced in the nitrogenase reaction, recovering electrons and producing ATP.

The structural and biochemical characteristics have been studied especially in nitrogenases that contain the transition metal molybdenum (Mo-nitrogenases). Other, less common and less studied, variants replace vanadium (V-nitrogenases) for

Fig. 7 Nitrogenase and nitrogenase genes. (A). Nitrogenase structure at 1.9 Å resolution. Two molecules of the dinitrogenase reductase NifH dimer are bound to a central dinitrogenase heterotetramer (2 NifDK). Substrate reduction takes place on FeMo-co (depicted), which is buried within each of the two α (NifD) subunits of dinitrogenase. Also shown is one of the P clusters that facilitate transfer of electrons from dinitrogenase reductase to the FeMo-co. (B). Genetic organization of *nif* (nitrogen fixation) genes in *Azotobacter vinelandii* and *Paenibacillus* sp., examples of *nif* clusters containing a large number or a minimal set of *nif* genes, respectively, and in *Anabaena variabilis*. In the latter, note the split *nifD* gene, interrupted by an intervening genetic element that is excised upon heterocysts differentiation. Common *nif* genes are identified: *nifHDK*, *nifEN* and *nifB*. Regulatory genes *nifLA* are also shown for *A. vinelandii*.

molybdenum. A third type of nitrogenase contains iron instead of Mo or V. Since all of the above variants also contain additional Fe, the latter are known as Fe-only nitrogenases.

Mo-nitrogenase is actually a complex of two metalloenzymes. The largest, dinitrogenase (also known as MoFe protein), is a ca. 250 kDa heterotetramer ($\alpha_2\beta_2$) organized as two $\alpha\beta$ heterodimers (Fig. 7(A)). Each dimer contains a unique iron-molybdenum cofactor (FeMo-co) on the α subunit, the active site of substrate binding and reduction, and a unique Fe-S cluster, the P cluster, at the α - β subunit interface. The smaller enzyme, dinitrogenase reductase (also known as Fe protein), is a ca. 46 kDa α_2 homodimer (Fig. 7(A)). Each subunit contains an ATP/ADP binding site and both subunits are bridged by a 4Fe-4S cluster.

The role of dinitrogenase reductase is to deliver electrons to dinitrogenase, one at a time. In turn, dinitrogenase reductase is reduced by a cellular source of high-energy electrons, often ferredoxins or flavodoxins, that varies among diazotrophs and is often a reflection of its particular lifestyle. Once reduced, dinitrogenase reductase transiently associates with dinitrogenase and hydrolyzes 2 molecules of ATP to ADP in order to transfer one electron to dinitrogenase. After transfer, the oxidized enzyme dissociates and replaces the ADPs by ATPs, getting ready to be reduced again. Electrons received by dinitrogenase are stored in the protein and eventually transferred to the substrate in FeMo-co through the P clusters. Therefore, eight interlocking catalytic cycles

of dinitrogenase reductase are required per cycle of dinitrogenase in what is one of the slowest enzymatic rates (ca. 1 cycle per second). Given these characteristics, and the fact that, despite the availability of high resolution structures, bound substrate and intermediates have not been unequivocally visualized, it is not surprising that details of the nitrogenase mechanism have yet to be ascertained.

The two complex metal cofactors of dinitrogenase, FeMo-co and P clusters, are unlike any other found in biological systems. Despite the fact that FeMo-co (and probably P clusters) can be extracted from the enzyme in active form, they are extremely labile, and their structure has only been solved within the enzyme. FeMo-co contains a [4Fe-3S] subcluster and a [3Fe-Mo-3S] subcluster separated by a C atom, probably a carbide, and a molecule of (R)-homocitrate coordinated to Mo through its 2-hydroxy and 2-carboxyl groups. FeMo-co synthesis and assembly require a large number of specific proteins, and its mechanism has been unraveled through the use of sophisticated in vitro systems with purified components and precursors. P clusters are [8Fe-7S] clusters that originate by specific, in situ reductive fusion of two standard [4Fe-4S] clusters. Both FeMo-co and P clusters confer oxygen sensitivity to dinitrogenase, which is rapidly inactivated and denatured upon exposure to air. Even higher oxygen sensitivity has been observed with dinitrogenase reductase, despite the fact that its [4Fe-4S] cluster is similar to clusters present in other, oxygen-resistant proteins.

Although fragmentary, the available evidence suggests that V-nitrogenases and Fe-only nitrogenases are evolutionarily related to the more widespread Mo-nitrogenases, that their general architecture, synthesis and mechanism are similar, and that they may reflect adaptations to diazotrophy under conditions where Mo may become limiting for nitrogen fixation. In this regard, several considerations could be taken into account: (a) the catalytic inefficiency of nitrogenase (see above) is often compensated by the synthesis of very high levels of the enzyme, that can amount to over 20 % of the total cell protein; (b) Mo-depleted ecosystems exist, such as some acidic soils and open oceanic waters; (c) the catalytic efficiency of V- and Fe-nitrogenases is lower than that of Mo-nitrogenases; and (d) one or both of these "alternative" systems can be found in diazotrophs that also possess a Mo-nitrogenase. In those cases, the more efficient Mo nitrogenase is expressed when Mo is available, and the several systems can share some of their accessory components, such as those related to metal cofactor synthesis.

Genetics and Regulation

The genetic determinants for nitrogenase and nitrogenase maturation proteins have been studied in a few model systems, notably *K. pneumoniae* and *A. vinelandii* (Fig. 7(B)). Comparative DNA sequence analyses, stimulated by the recent explosion in prokaryotic genome sequencing, have shown that many of the *nif* (nitrogen fixation) determinants, notably those encoding structural proteins, are strongly conserved in diazotrophs. Analysis of their functions has been facilitated by their organization in tight gene clusters containing co-regulated operons. The number of *nif* genes in diazotrophs is variable, from over 30 in *A. vinelandii*, 20 in *K. pneumoniae*, and down to nine in Firmicutes (Fig. 7(B)) and some archaea, with a minimum set of six *nif* genes conserved throughout. These include *nifH*, *nifD*, *nifK*, *nifE*, *nifN*, and *nifB*. The first three encode the dinitrogenase reductase structural subunit and the α and β subunits of dinitrogenase, respectively, while the last three are involved in FeMo-co synthesis: NifE and NifN are structural homologues of NifD and NifK, respectively, and form a $\alpha_2\beta_2$ heterotetramer that acts as a scaffold on which FeMo-co is assembled from a precursor cluster (NifB-co) synthesized by NifB. Other *nif* genes are involved in Mo metabolism, synthesis of Fe-S cluster precursors and homocitrate, on one hand, and nitrogenase assembly and maturation, electron transfer to nitrogenase and regulation, on the other. Some of these functions, such as the first three, can be provided by the housekeeping cellular machinery, although it is not uncommon to find *nif*-specific determinants of those functions, such as in the case of Fe-S cluster synthesis, in view of the demands that high levels of nitrogenase synthesis can impose on housekeeping elements.

As is the case with electron transfer to nitrogenase -highly dependent upon specific metabolic lifestyles- different models of nitrogen fixation regulation exist, so as to adapt nitrogen fixation expression to specific cellular contexts. Besides the high energy requirements, the enzyme is strongly and irreversibly inactivated by oxygen. Therefore, it is not surprising that diazotrophs prefer to use fixed nitrogen sources over dinitrogen, and that nitrogenase is usually tightly regulated by the nitrogen and oxygen status of the cell, either directly or indirectly. Regulation of nitrogen fixation occurs mainly at the transcriptional level rather than at the activity level. Contrary to many biosynthetic enzyme systems, nitrogenase is not subject to end-product inhibition, and oxygen simply inactivates the enzyme irreversibly.

Transcriptional regulation of nitrogen fixation has been studied in detail in proteobacteria (*K. pneumoniae*, *A. vinelandii* or the Rhizobia). Promoters of *nif* genes are dependent on an alternative sigma factor (σ^{54}) that recognizes consensus sequences at positions -24 and -12. σ^{54} -RNA polymerase holoenzyme can initiate transcription only after σ^{54} interacts with a transcriptional activator bound to upstream enhancer sequences. In the case of *nif* promoters, this activator is NifA, a homodimeric protein that belongs to the ATPase AAA+ superfamily and that, using ATP hydrolysis, determines a conformational change in σ^{54} that results in the formation of a transcriptionally competent RNA polymerase-promoter open complex. This strategy is advantageous in that it ensures that no low-level transcription can occur in the absence of NifA, and in that it provides a target, NifA, for signal transduction. In some organisms, notably the Rhizobia, NifA is able to sense the oxygen status directly, becoming inactivated under aerobic conditions, and even the N status. In others, such as in *K. pneumoniae* and *A. vinelandii*, *nifA* is cotranscribed with *nifL*. The NifL protein has the ability to bind to NifA, inactivating it in response to environmental signals, such as the redox, N and C status of the cell. In that respect, the NifLA pair resemble two-component regulatory systems. However, although it is possible that they may have evolved from such a system (the identifiable remnants of a histidine-protein kinase domain are present in NifL), their ability to integrate these disparate environmental signals, not only within NifL, but in some cases also within NifA, makes this an unusual

regulatory pair. Transcription of *nifA* (or *nifLA*) can, in turn, be subjected to environmental signal control in a cascade-like manner, thus ensuring an amplification of the signal compatible with the need for a tight, highly responsive regulation of nitrogen fixation.

This specific picture of nitrogen fixation regulation, drawn from studies of proteobacteria, is not shared by many other diazotrophs. Thus, although detailed knowledge of specific regulatory mechanisms is lacking in many cases, proteins homologous to NifA proteins are missing from the genomes of diazotrophs as diverse as the archaea and the Firmicutes, among others. However, the basic tenets of expression in the absence of fixed nitrogen sources and oxygen still hold in most cases. The *nif* genes from methanogenic archaea and Firmicutes appear to be regulated by transcriptional repression, rather than induction. Cyanobacteria also lack NifA and appear to use a redox-sensitive transcriptional activator, CnfR. In strains without heterocysts (cells specialized in N₂ fixation), CnfR is expressed under N starvation, while in heterocyst-forming strains, it is expressed only in heterocysts (see Section “The heterocyst”).

A further aspect of regulation concerns the alternative V- and Fe-nitrogenases, especially when they coexist with a Mo-nitrogenase system, such as in *A. vinelandii* and the cyanobacterium *Anabaena variabilis*. *A. vinelandii* is unique in containing all three, Mo-, V-, and Fe-only nitrogenase systems. The alternative systems are regulated by NifA orthologues, VnfA and AnfA, respectively, in response to N and O₂ signals, and by a further, hierarchical regulation with preference for Mo-nitrogenase > V-nitrogenase > Fe-only nitrogenase. Rather than sensing the transition metal directly, regulation appears to respond to the efficiency of the nitrogenase system in a not well-understood cross-talk that implicates NifA, VnfA and AnfA. *A. variabilis* contains two Mo-nitrogenases and one V-nitrogenase. The main Mo- and the V-nitrogenase systems are hierarchically expressed in heterocysts, while the second Mo-nitrogenase is only expressed under anaerobic conditions, and thus in all the cells in the filament.

Finally, it is worth noting that a post-transcriptional regulatory mechanism of nitrogenase activity operates in some α -proteobacteria, such as *Azospirillum brasilense*, and purple photosynthetic bacteria. In these bacteria, dinitrogenase reductase is reversibly inactivated by ADP-ribosylation in response to ammonium or lack of energy (darkness in photosynthetic bacteria or anaerobiosis in *A. brasilense*).

Mechanisms of Protection of Nitrogenase Against Oxygen

The extreme oxygen sensitivity of nitrogenase proteins and cofactors is probably a reflection of the fact that they evolved before the Great Oxygenation Event. Nonetheless, the physiological and ecological advantages afforded by the ability to fix nitrogen in fixed N-depleted environments, even in the presence of air, have resulted in the acquisition of a wide range of adaptations to protect nitrogenase from oxygen. The simplest case is that of the obligate anaerobes, such as archaea and the clostridia. These diazotrophs cannot live in the presence of oxygen even if they are not fixing nitrogen, therefore no special adaptations of nitrogenase to oxygen is required or has been selected. Facultative anaerobes, such as enterobacterial diazotrophs, can fix nitrogen only under fermentative conditions, but their respiratory systems have been shown to help scavenge oxygen by using it as electron acceptor.

A large number of chemoorganotrophic, diazotrophic bacteria are dependent on respiration with oxygen as terminal electron acceptor to obtain energy, and can only fix nitrogen under decreased oxygen tension, where the combined effect of physical barriers to oxygen diffusion and respiratory consumption of the diffused oxygen result in near-anoxic conditions compatible with nitrogenase expression and activity. This is the case of the Rhizobia, that associate with legumes to fix nitrogen within a special root organ, the nodule, where root and bacterial respiration contribute to decrease oxygen levels. However, the obligatory need for oxygen as terminal electron acceptor in the Rhizobia has resulted in specific molecular adaptations of the symbiosis, such as the accumulation of a legume hemoglobin, leghemoglobin, that provides the bacteria with a steady supply of oxygen at low levels, or the expression of a high-oxygen-affinity terminal respiratory oxidase that allows the bacteria to obtain energy at these low oxygen levels.

A. vinelandii exemplifies the best-studied case of strictly aerobic diazotrophy in unicellular bacteria. Complete protection of nitrogenase against oxygen is provided, again, by a combination of structural oxygen diffusion barriers (cell envelopes, exopolysaccharides) and respiratory protection (increased respiration mediated by several redundant terminal oxidases with high capacity and high affinity towards oxygen), which together result in an adequate decrease in dissolved oxygen levels and diffusion rates. It is worth noting that one of these high capacity oxidases -a quinol oxidase- can become uncoupled from ATP synthesis and thus work as a combustion machine, provided that reducing power is not limiting. A further adaptation to diazotrophy under air is the presence in *A. vinelandii* of the Fe/S II protein, which can bind to nitrogenase forming an oxygen-resistant complex that can preserve the integrity of nitrogenase under transitory episodes of increased oxygen.

Protection in oxygenic phototrophs (Cyanobacteria)

In cyanobacteria, the issue of protection of the nitrogenase system from oxygen is specially demanding because, as oxygenic phototrophs, they not only have to cope with ambient oxygen but also with that produced intracellularly by oxygenic photosynthesis. Nevertheless, the capacity to fix N₂ is widespread in the cyanobacterial phylum, and different strains have evolved different strategies to fix N₂ in oxic environments, although some strains can do so only under micro-oxic or anoxic conditions. As an example of the latter, cyanobacteria of the genus *Oscillatoria* can fix N₂ while performing H₂S- and photosystem I-dependent anoxygenic photosynthesis under anaerobic conditions. Besides that, well known strategies for protection against intracellular O₂ are based on temporal or spatial separation of the processes of N₂ fixation and oxygenic photosynthesis. Thus, in many filamentous and unicellular cyanobacteria, N₂ fixation is restricted to the dark periods when subjected to a diel cycle, and likely under natural conditions (as shown for the marine unicellular organism *Chroocosphaera* sp.). In the dark period, N₂ fixation

can coincide with active respiration, which has a dual function in provision of energy and oxygen scavenging. As an example, in the unicellular *Cyanothece* sp., photosynthesis, ATP synthase, CO₂-fixation and glycogen biosynthesis genes are expressed in the light periods, whereas glycogen degradation, respiration and *nif* genes are expressed in the dark periods. This pattern of expression involves circadian regulation. In contrast, in the filamentous cyanobacterium *Trichodesmium* sp., a globally-relevant N₂ fixer in the oceans, N₂ fixation peaks in the light periods during diel cycles. Although the mechanism of nitrogenase protection is not clear, it is debated whether N₂ fixation is confined to cells in a central stretch of the filament that would have reduced oxygen content, perhaps aided by temporal segregation of CO₂ and N₂ fixation during the day. Further specialization is found in some filamentous cyanobacteria, included in a defined phylogenetic clade, that can produce heterocysts, which are cells specialized for the fixation of N₂. In these strains, heterocysts are the only cells of the filament that, under oxic conditions, express nitrogenase (Fig. 8).

Fig. 8 Heterocyst-forming cyanobacteria. (Top) Light micrograph of filaments of *Anabaena* sp. strain PCC 7120 showing chains of vegetative cells, which perform CO₂ fixation through oxygenic photosynthesis and divide, and intercalary heterocysts, terminally differentiated cells that carry out N₂ fixation. (Bottom) Transmission electron micrograph of a terminal heterocyst and two adjacent vegetative cells. The intracellular membranes in vegetative cells (thylakoids) are the sites of oxygenic photosynthesis, and the carboxysomes are the sites of CO₂ fixation. In the heterocysts, carboxysomes are missing and the intracellular membranes are largely reorganized to form the “honeycomb” membranes, which are sites of active respiration and anoxygenic photosynthesis. The heterocyst has, deposited outside of the outer membrane, a special cell envelope that contains heterocyst-specific glycolipids (Hgl) and polysaccharides (Hep). At the heterocyst poles, cyanophycin (multi-L-argininyl-poly [L-aspartic acid]) accumulates as a large cell inclusion known as cyanophycin granule (CGP) that is also observed by light microscopy (see above).

The heterocyst

The differentiation of a vegetative cell into a heterocyst takes place in response to N deprivation and involves extensive structural and biochemical changes to provide suitable sites for efficient N_2 fixation. Morphological changes that take place during differentiation include the deposition of specific glycolipid and polysaccharide cell envelope layers to limit gas, including oxygen, penetration into the cell cytoplasm. Indeed, it has been proposed that the main path for N_2 entrance into the heterocyst is a differentiated, membrane protein structure at the heterocyst poles that could modulate gas diffusion rates. Also, conspicuous reorganization of the photosynthetic membranes, which is concomitant with loss of photosystem II function (and thus of oxygenic photosynthesis), takes place during differentiation.

Biochemically, the photoautotrophic metabolism of the vegetative cell is turned into a heterotrophic metabolism in the heterocyst. This transition is based on the loss of photosynthetic CO_2 fixation (which is catalyzed by ribulose-bisphosphate carboxylase/oxygenase [RubisCo]), expression of a specific invertase for sucrose catabolism, increased levels of the oxidative pentose phosphate cycle enzymes, and expression of specific terminal respiratory oxidases. Indeed, the heterotrophic metabolism of heterocysts relies on sugars donated by the neighboring vegetative cells, which also provide carbon skeletons for the incorporation of the ammonium resulting from N_2 reduction. In turn, heterocysts transfer fixed nitrogen in the form of amino acids (including a dipeptide, β -aspartyl-arginine) to the vegetative cells. Thus, under diazotrophic conditions the organismic unit of these cyanobacteria is a filament constituted by different cell types with specialized metabolic functions that exchange nutrients and regulatory molecules (see later in this section), representing true pluricellular bacteria (Fig. 8).

At the genetic level, heterocyst differentiation involves the sequential action of the products of multiple regulatory and structural genes, leading to the establishment of a gene expression pattern differing conspicuously from that taking place in the vegetative cells. Two transcription factors are required for triggering differentiation: the global N-regulator NtcA (see Section "Nitrogen Control"), and HetR. At the initiation of differentiation, basal levels of NtcA are activated by the increased levels of 2-oxoglutarate that result from an increased C-to-N cellular balance upon N deficiency, and the genes *ntcA* and *hetR* are activated in a mutually- and self-dependent manner, which leads to the establishment of high levels of both regulators. Remarkably, activation of the expression of the genes encoding these two main regulators, as well as of many of their regulated genes, takes place in the specific cells of the filament engaged in differentiation. Thus, many genes involved in heterocyst differentiation and function present spatiotemporal specificity for activation, including the *nif* genes, which are expressed only in mature heterocysts. Molecular events contributing to this pattern include the remarkable occurrence of complex promoter regions for many of those genes, which bear several successive promoters with different requirements for NtcA and HetR, and the participation of secondary regulators that are expressed at precise stages during differentiation, some of which increase the expression or activity of NtcA or HetR (Fig. 9).

Fig. 9 Regulation of heterocyst differentiation. Nitrogen deprivation elicits an increase in the 2-oxoglutarate cellular levels, and 2-oxoglutarate binds and activates NtcA, which was present at low concentration during growth with combined nitrogen, initiating a loop of mutual and auto-induction of the genes *hetR* and *ntcA*, which initially takes place in clusters of cells. Concomitantly, the *patS* gene is expressed in specific cells that have initiated differentiation, and the primary gene product is processed to render the PatS morphogen, which is transferred to neighboring cells inhibiting their differentiation and leading to single cell selection. Structural proteins and secondary regulators are sequentially expressed, with a direct or indirect requirement for NtcA and HetR, that promote differentiation into heterocysts. In the diazotrophic filament of *Anabaena*, heterocysts, which fix N_2 , are separated by stretches of ca. 10 vegetative cells, which fix CO_2 . Heterocysts donate organic nitrogen to the vegetative cells, while the vegetative cells transfer organic C to the heterocysts.

Heterocysts are not randomly-distributed in the cyanobacterial filament. In the case of strains such as those of the genera *Anabaena* or *Nostoc*, heterocysts are flanked by stretches of ca. 10 vegetative cells, an adequate pattern to fulfill the nutritional interdependence between the two cell types. The PatS morphogen is a key element in establishing the heterocyst distribution pattern. The *patS* gene is induced early in differentiating cells and encodes a primary product of 17 amino acids that is processed to render the active molecule (a C-terminal peptide of likely seven residues), which is a HetR (and thus a differentiation) inhibitor. Indeed, PatS is transferred from source cells, where the *patS* gene is expressed, to neighboring cells, setting a concentration gradient with higher levels in the cells adjacent to the source cell, within which the concentration remains negligible, and diminishing with distance from there on (Fig. 9). The gradient of PatS peptide away from the heterocyst appears to create an inverse gradient of HetR to determine the pattern of cellular differentiation in each filament.

Nitrogen Storage

Although scarcely studied, nitrogen storage could take place in different bacteria. Only one specific nitrogen reservoir is known, the cyanophycin granules that will be discussed here. Nonetheless, the general protein pool of a bacterium, or specific proteins such as phycobiliproteins in the case of cyanobacteria, can constitute nitrogen reservoirs made available by protein turnover under nitrogen deficiency.

In most cyanobacteria, cyanophycin represents a dynamic reservoir of nitrogen that is accumulated in the form of cytoplasmic granules. Cyanophycin accumulates under conditions of unbalanced growth that do not involve N starvation, e.g., under phosphate or sulfur starvation or high CO₂ supply. In diazotrophic strains that temporarily separate oxygenic photosynthesis and N₂ fixation, cyanophycin accumulation may coincide with the periods of N₂ fixation. In filamentous heterocyst-forming strains, cyanophycin is conspicuously accumulated at the polar regions of the heterocysts (Fig. 8), representing a pool of fixed N *en route* to the vegetative cells. First thought to belong only to cyanobacteria, genes encoding cyanophycin-metabolism enzymes have later been identified in the genomic sequence of many other bacteria with different metabolic options including phototrophy, aerobic or anaerobic respiration, chemolithoautotrophy or fermentation. As in cyanobacteria, cyanophycin is accumulated under phosphate limitation in, e.g., *Acinetobacter* sp. Interestingly, cyanophycin is considered a source of products with potential interest in the chemical and pharmacological industries (biopolymers, natural food additives, therapeutic amino acid supplements), and projects aimed at increasing the accumulation of cyanophycin in several bacteria, as well as the expression of cyanophycin synthesizing enzymes in heterologous hosts, including yeast and plant plastids, have been developed.

Cyanophycin Metabolism

Cyanophycin is made of polypeptide chains of variable length that contain arginine residues linked to a polyaspartate backbone in a nearly 1:1 (Arg:Asp) ratio. The cyanophycin polypeptides are water insoluble and form granules. Cyanophycin is non-ribosomally synthesized by cyanophycin synthetase, which catalyzes both the elongation of the backbone by addition of L-Asp forming an α -peptide bond, and the addition of L-Arg to the β -carboxyl group of Asp making an isopeptide bond. Both reactions require ATP. The enzyme is a homodimer, the product of the *cphA* gene, with two predicted catalytic sites: one C-terminal site for the incorporation of Asp, and one N-terminal site for the addition of Arg. Cyanophycin degradation takes place in two sequential steps. First cyanophycinase, a C-terminal exopeptidase, a dimer of the product of the *cphB* gene, excises a β -Asp-Arg dipeptide. The dipeptide is further hydrolyzed to the constituent amino acids by isoaspartyl dipeptidase, which is a dimer of two different subunits resulting from autoproteolytic cleavage of the precursor gene product, and which is similar to plant asparaginases. While the *cphA* and *cphB* genes are frequently clustered, the gene encoding isoaspartyl dipeptidase is located in a different chromosome location.

Some bacteria are able to use cyanophycin as a carbon source for growth in a process that involves extracellular cyanophycinases. The enzyme from *Pseudomonas anguilliseptica* (CphE) has been purified and shows high specificity for cyanophycin to produce also a β -Asp-Arg dipeptide, although it exhibits only ca. 27% identity to the intracellular cyanobacterial cyanophycinase.

Regulation of Cyanophycin Accumulation

In both the unicellular cyanobacterium *Synechocystis* sp. PCC 6803 and the filamentous heterocyst-forming cyanobacterium *Anabaena* sp. PCC 7120, the P_{II} protein factor (GlnB) influences cyanophycin accumulation. In the former case, the effect has been shown to involve activation of N-acetylglutamate kinase (NAGK) -a key enzyme of the arginine biosynthesis pathway- by unphosphorylated P_{II}, which leads to increased production of arginine under conditions of low C-to-N balance.

In several strains of *Anabaena* grown under diazotrophic conditions, cyanophycin synthetase and cyanophycinase activities are higher in heterocysts than in vegetative cells. In *Anabaena* sp. PCC 7120, the transcriptional regulator NtcA has been shown to orchestrate this spatial regulation from a complex promoter arrangement. In contrast, aspartyl dipeptidase levels are higher in vegetative cells than in heterocysts. Accordingly, cyanophycin synthesized at the expense of fixed N in the heterocyst is transiently accumulated in polar granules and hydrolyzed to β -Asp-Arg dipeptide, which is transferred to the vegetative cells to be further hydrolyzed to Asp and Arg to be used for metabolism. Thus, the dipeptide represents a nitrogen vehicle in the diazotrophic filament.

Nitrogen Control

In many bacteria, a hierarchy in the order of assimilation of nitrogen sources is established when more than one is available. In many cases ammonium represents the preferred nutrient, given that its assimilation implies a lower energetic cost than that of nutrients that have to be intracellularly transformed into ammonium. Indeed, in most bacteria ammonium exerts a negative effect on the expression of genes encoding elements of the pathways for assimilation of other nitrogen sources, a global regulatory circuit that is referred to as nitrogen control (N control). At the molecular level, both the array of protein factors (transporters, enzymes, pathway-specific regulators) that are subjected to N control, as well as the mechanism of ammonium-promoted down-regulation, vary among different bacteria. However, several basic schemes can be recognized, as described below. A key issue regarding N-control circuits deals with signaling of the N status of the cell to influence the activity of the N-control regulators. In general, high levels of 2-oxoglutarate which, as mentioned above, is a substrate for the incorporation of ammonium into glutamate and glutamine, are indicators of N deficiency, whereas additionally high levels of glutamine may be sensed as an indicator of N sufficiency. Whether both indicators or just 2-oxoglutarate are used depends on the metabolic characteristics of the different bacteria.

The *E. coli* Cascade System

The genetic and biochemical mechanisms of nitrogen control have been studied in detail in the *E. coli* model system, but some of its general characteristics are conserved in the Proteobacteria. In addition, the N-control system shares sensors and signal transduction mechanisms with those regulating the activity of the principal first enzyme for ammonium incorporation into C skeletons, glutamine synthetase (see Section “Incorporation of intracellular ammonium into carbon skeletons”, Regulation).

In *E. coli*, the *glnA* gene encoding GS is organized in an operon together with the genes for a N-responsive, two-component regulatory system, the Ntr system (Fig. 10). The sensor/transmitter component, NtrB, is a protein kinase/phosphatase that can specifically phosphorylate or dephosphorylate the receiver/regulator component, NtrC. When phosphorylated, NtrC acts as a transcriptional activator of the main *glnA* promoter, while dephosphorylation inactivates it. NtrB is able to autophosphorylate at the expense of ATP, and to transfer this phosphoryl group to NtrC, therefore activating it in the absence of any other component. However, the NtrB activities are modulated by its interaction with the P_{II} factor GlnB.

P_{II} proteins are organized as trimers, and each subunit can bind one molecule of 2-oxoglutarate. Under N-excess most of the 2-oxoglutarate binding sites in P_{II} proteins will be empty, with the reverse being true under N-deficiency. In the case of GlnB, as a result of a cellular situation of N excess, many of the trimers will contain a single molecule of 2-oxoglutarate. This form of GlnB will bind to NtrB, with two consequences: (i) inhibition of NtrB autophosphorylation; and (ii) stimulation of the NtrB-mediated NtrC-P dephosphorylation. As a result, the levels of NtrC-P will drop and transcriptional activation of the main *glnA* promoter will stop. A large number of N assimilation genes are also transcribed from NtrC-dependent promoters, which makes NtrBC a global regulatory system. As with NifA (see Section “Nitrogen fixation”, Genetics and Regulation), NtrC-P binds to upstream activator sequences of σ^{54} -dependent promoters, thus ensuring that no transcriptional leakage occurs in the absence of the activator.

Fig. 10 The *Escherichia coli* cascade system of N control. Activity of the two-component Ntr regulatory proteins, NtrB and NtrC, is regulated by phosphorylation. NtrB can be autophosphorylated at the expense of ATP, and then transfer this phosphoryl group to NtrC (upper central part). NtrC-P can activate transcription through binding to upstream activating sequences (UAS) of N-regulated promoters, in particular the promoter of the *glnA-ntrBC*, but also those of operons whose gene products allow the cell to assimilate alternative nitrogen sources (lower part). The GlnB and GlnK P_{II} proteins control the levels of NtrC-P. The completely dephosphorylated form of the proteins bound to one 2OG (GlnB-2OG and GlnK-2OG), found in the cell when levels of glutamine are high (N excess, Fig. 4), bind to NtrB and stimulate dephosphorylation, and hence deactivation, of NtrC (upper right part). In addition, GlnB-2OG inhibits the autophosphorylation activity of NtrB (upper left part), thus ensuring that no further phosphorylation of NtrC-P can take place. Yellow diamonds, 2-oxoglutarate (2OG).

The GlnB > NtrB > NtrC > target promoter cascade is further controlled at the level of the GlnB sensor. In addition to binding 2-oxoglutarate, each monomer in the trimer can be covalently modified by uridylation through the activity of the GlnD protein. GlnD is a bifunctional uridylyltransferase/uridylyl-removing enzyme (UTase) that can apparently sense the cellular levels of glutamine. High glutamine levels determine deuridylation of GlnB, while complete uridylation is observed at low glutamine levels. Since binding of 2-oxoglutarate -and probably ADP- to GlnB is required for uridylation, GlnB appears to be a sensor where different signals (glutamine, 2-oxoglutarate, energy charge) can be integrated.

A further level of complexity arises from the existence of another P_{II} protein, GlnK, a GlnB paralog. While GlnB is always present in the cell, *glnK* transcription is under N control and GlnK is present only under N-deficiency. Both proteins can bind 2-oxoglutarate, can interact with NtrB, and be a substrate of UTase, while only GlnK regulates the AmtB channel activity (see Section "Regulation of *amtB*", above).

The NtcA Circuit of Cyanobacteria

The NtcA regulator was identified as the product of the gene inactivated in cyanobacterial mutants unable to use inorganic nitrogen sources (nitrate, nitrite or N₂) other than ammonium, and it turned out to have a universal distribution in the cyanobacterial phylum. NtcA belongs to the family of transcriptional regulators that also includes CAP (catabolite activator or cAMP receptor protein -CRP) from *E. coli*. As other members of this family, NtcA bears in its C-terminal part a helix-turn-helix motif for binding to DNA at sites with a palindromic structure, which in the case of NtcA includes the sequence signature GTAn₆TAC. NtcA can act as a transcriptional activator or repressor depending on the location of the NtcA-binding site in the regulated promoter, and in the most common NtcA-activated promoters, the binding site is separated by ca. 22 nucleotides from a -10 promoter determinant (consensus: TAn₃T). This promoter structure is similar to that of Class II bacterial-activated promoters, in which the binding site of the regulator substitutes for the -35 determinant that is found in constitutive promoters. Besides this, in some other NtcA-activated promoters, the NtcA-binding site is located further upstream from the -10 determinant (Class I activated promoters) or present degenerate NtcA-binding sites requiring the participation of NtcA co-activators. Worth mentioning is the principal role of NtcA in determining the spatiotemporal specificity of activation of genes involved in heterocyst differentiation by acting on different types of NtcA-dependent promoters included in complex promoter regions, as mentioned above.

Because cyanobacteria lack 2-oxoglutarate dehydrogenase, 2-oxoglutarate is mainly used through the GS/GOGAT cycle (see Section "Incorporation of intracellular ammonium into carbon skeletons"). Thus, 2-oxoglutarate levels depend not only on CO₂ assimilation through the Calvin/Benson cycle but also on ammonium assimilation through the GS/GOGAT cycle. As such, 2-oxoglutarate levels, which are low in the presence of ammonium, are a good indicator of the C-to-N balance of the cell. Indeed, 2-oxoglutarate has been shown to bind to NtcA, to stimulate NtcA-binding to DNA in regulated promoters, and to be required at the step of promoter melting to establish the open promoter complex for transcription initiation in Class II promoters.

Regarding NtcA targets, a plethora of genes of different N-assimilation pathways and heterocyst differentiation have been individually characterized as regulated by NtcA. Besides that, a global study by chromatin immunoprecipitation has identified more than 2000 NtcA targets in the genome of *Anabaena* sp. PCC 7120, including promoter regions of genes involved in N assimilation but also in other cellular functions such as photosynthesis, central metabolism or DNA replication and repair. This exceptional abundance of DNA binding sites suggests that besides being a global transcriptional regulator, NtcA could serve a structural function as a genome-wide DNA shaper.

Gram-Positive Bacteria

The Gram-positive bacteria include organisms for which relevant information on nitrogen control is available. These organisms are *B. subtilis* and the Actinobacteria *Streptomyces coelicolor*, *Corynebacterium glutamicum* and *Mycobacterium* spp., including the non-pathogenic species *M. smegmatis*.

Bacillus subtilis

The soil, sporulating bacterium *B. subtilis* has been intensively investigated as a model of bacterial development and cell biology. In the presence of glucose as a carbon and energy source, the preferred nitrogen source of *B. subtilis* is glutamine followed by arginine and ammonium. *B. subtilis* expresses two MerR-family transcription factors, TnrA and GlnR, that execute N control in concert with glutamine synthetase (GlnA). MerR-family transcriptional regulators generally contain a helix-turn-helix motif for DNA-binding in their N-terminal region, followed by a coiled-coil domain and a C-terminal effector-binding region that is specific to the effector recognized. TnrA and GlnR bind to similar DNA sites of consensus sequence TGTnAnATTTnTnACA, which results in an overlap of their respective regulons. However, while TnrA acts under conditions of nitrogen limitation, GlnR acts under conditions of nitrogen sufficiency. Under nitrogen deficiency, TnrA is positively auto-regulatory and regulates at least 35 transcriptional units. TnrA activates the expression of operons such as *nrgAB* encoding the ammonium-scavenging protein AmtB and its inhibitor GlnK, respectively, *ureABC* encoding urease or *nasBC* and *nasDEF* encoding nitrate assimilation proteins, and represses operons such as *gltAB* encoding GOGAT or *glnRA* encoding the GlnR repressor and glutamine synthetase. Under nitrogen sufficiency, glutamine-inhibited glutamine synthetase (GlnA-glutamine) binds to TnrA blocking its DNA-binding activity (and, hence, impeding its regulatory roles) and to GlnR promoting repression of operons such as *ureABC* or *glnRA* itself as well as the *tnrA* gene. GlnA-glutamine-activated GlnR can indeed bind to a wide number of genomic sites, implying that it is part of complex transcriptional

Fig. 11 Nitrogen control in *Bacillus subtilis*. (Top) Scheme of the basic actions of the MerR-family transcriptional regulators TnrA and GlnR. Under N deprivation, TnrA can act as an activator and a repressor of gene expression. Under nitrogen sufficiency (high glutamine cellular levels), a glutamine synthetase (GS)-glutamine complex binds to TnrA blocking its transcriptional activity and to GlnR allowing it to act as a repressor. (Bottom) The LysR-family transcriptional regulator GltC activates expression of the *gltAB* operon encoding glutamate synthase (GOGAT) under N deficiency (high 2-oxoglutarate [2OG] levels). In response to high glutamate levels, GltC acts instead as a repressor of *gltAB* and is blocked by binding of the catabolic enzyme glutamate dehydrogenase (GDH).

regulatory networks. GlnR binds DNA as a dimer, and the C-terminal domain of GlnR (which differs from that of TnrA) has a role inhibiting GlnR dimerization and DNA binding; interaction of this domain with GlnA-glutamine releases such inhibition permitting binding to DNA (Fig. 11). This regulation ensures that operons encoding proteins for the assimilation of nitrogen sources alternative to glutamine, such as *ureABC*, are expressed under nitrogen deficiency and fully repressed under nitrogen sufficiency.

Another layer of N control in *B. subtilis* is exerted by GltC, a LysR-family transcriptional regulator that alternatively binds 2-oxoglutarate or glutamate to activate or repress, respectively, the *gltAB* operon. Activation and repression involves binding to different DNA sites in the intergenic region between the divergent *gltAB* operon and *gltC* gene. Further, the *gltC* gene is negatively auto-regulated and also repressed by TnrA, and the GltC protein is inhibited by interaction with the enzyme glutamate dehydrogenase in the presence of glutamate (Fig. 11). This complex regulation ensures maximal expression of *gltAB* when 2-oxoglutarate is available and glutamate scarce.

This brief summary illustrates the complex system utilized by *B. subtilis* to respond to nitrogen availability and the C-to-N balance. Of special interest is the integration in this system of so-called trigger enzymes, proteins that perform both enzymatic and regulatory functions. Thus, the nitrogen metabolism enzymes glutamate dehydrogenase and glutamine synthetase interact with transcriptional regulators influencing their DNA-binding activities.

Actinobacteria

The Streptomycetes are the most important antibiotic-producing bacteria. A model strain for this bacterial group in laboratory work is *S. coelicolor*, which can use a wide range of nitrogen sources including ammonium, nitrate, urea, amino acids and some amino sugars. Nitrogen control is executed by GlnR, which is an orphan OmpR-family response regulator unrelated to *Bacillus* GlnR. The expression of *S. coelicolor* *glnR* is regulated by the availability of nitrogen, as it is induced under nitrogen limitation and repressed under nitrogen excess. The GlnR protein produced under nitrogen limitation acts as a dimer activating or repressing different genes. GlnR frequently binds to two tandem DNA boxes with consensus sequence gTnAc-n₆-GaAAC-n₆. Genes activated by GlnR include *amtB* and *glnA*, and genes repressed include *ureA* and *gdhA*, whose expression may be not necessary under nitrogen limitation in this bacterium. Interestingly, GlnR regulates the expression of many carbon assimilation as well as nitrogen assimilation genes.

C. glutamicum has importance in the biotechnological industry as a producer of amino acids, mostly glutamate and lysine. This bacterium shows the capability of assimilating a number of nitrogenous compounds including ammonium, urea or creatinine. Nitrogen control is executed in this organism by the TetR-family transcriptional regulator AmtR that, acting as a dimer, represses at least 33 genes. The AmtR-binding site has the consensus sequence ttCTATn₆AtAGat/aA. TetR-family proteins frequently respond to

small-molecule ligands that function as metabolic sensors. AmtR instead responds to the P_{II} protein GlnK. Under nitrogen deprivation, *C. glutamicum* GlnK is adenylylated in response to the increase of the cellular levels of 2-oxoglutarate. Whereas adenylylation/deadenylylation of GlnK is catalyzed by GlnD, the 2-oxoglutarate sensor appears to be GlnK itself. While an AmtR dimer binds to gene promoters repressing gene expression, adenylylated GlnK interacts with AmtR releasing it from DNA and, hence, preventing it from repressing gene expression.

Mycobacterium smegmatis contains both GlnR and AmtR orthologues, of which GlnR appears to be the general N-control protein. GlnR regulates the expression of over 100 genes by binding to about 50 DNA sites with consensus sequence G_N2AC_N6GnAACA, within which AC_N9AC appears to be essential. In contrast, AmtR seems to have some specific roles including repression of the urea assimilation operon in competition with activation of the operon by GlnR. Although less studied than in *M. smegmatis*, the response to nitrogen stress in *M. tuberculosis* appears to be mediated also by GlnR.

In conclusion, the Actinobacteria present two interesting variations in the regulation of gene expression in nitrogen control. *Streptomyces* GlnR appears to be regulated just at the level of its own expression, and *Corynebacterium* AmtR is regulated by interaction with a universal N-to-C balance (2-oxoglutarate) sensor, GlnK.

Concluding Remarks

As with so many other metabolic processes, bacteria display a bewildering diversity in their nitrogen assimilation capabilities, and in the way they regulate them. Bacteria, as a group, are able to effectively assimilate most mineral and organic nitrogen sources, from the simplest, exemplified by dinitrogen, which is among the most inert N compounds and that only bacteria (and archaea) can attack, to complex, man-made xenobiotics, exemplified by atrazine. Many of these capabilities are often found within the same cell under strict regulatory controls governed by economy considerations: N assimilation can be quite demanding energetically. As a result, when given a choice, bacteria prefer the least expensive N source, often ammonium, and organize the regulation of the activity and expression of N assimilation pathways accordingly. Inorganic and most organic N sources eventually yield intracellular ammonium that is incorporated into C skeletons as glutamate and glutamine. The N status of the cell is usually sensed in terms of concentration of 2-oxoglutarate, or the ratio 2-oxoglutarate/glutamine. These signals may be transmitted to a cascade of effectors that finely control both the activity of the key ammonium assimilatory enzymes (notably GS and the ammonium transporter) and their expression and that of alternative N assimilation pathways, often in hierarchical terms.

Glossary

Ammonification Generation of ammonium by decomposition of organic matter or by dissimilatory nitrate or nitrite reduction.

Ammonium assimilation Incorporation of ammonium into carbon skeletons to synthesize organic N-compounds for cell growth and metabolism.

Anammox Anaerobic oxidation of ammonium with simultaneous nitrite reduction to dinitrogen coupled to the generation of proton-motive force.

Comammox Complete ammonia oxidation to nitrate coupled to the generation of proton-motive force.

Denitrification Sequential respiratory reduction of nitrate to nitrite, nitric oxide, nitrous oxide and dinitrogen that generates proton-motive force.

Detoxification Transformation of a toxic compound into a less harmful or innocuous product.

Dissimilatory nitrate reduction to ammonium Reduction of nitrate, via nitrite, to ammonium for the generation of proton-motive force, redox balancing or nitrite detoxification.

Nitrate assimilation Reduction of nitrate, via nitrite, to ammonium for its incorporation into C-skeletons.

Nitrification Aerobic oxidation of ammonium to nitrite and nitrate coupled to the generation of proton-motive force.

Nitrifier denitrification Ammonia oxidation to nitrite coupled to nitrite denitrification performed by nitrifying bacteria or archaea.

Nitrogen fixation Reduction of dinitrogen to ammonium for its incorporation into C-skeletons.

Nitrogen mineralization Formation of inorganic nitrogen by degradation of organic N-compounds.

Respiration Process that couples electron transfer from a reduced compound to oxygen or an alternative electron acceptor with generation of proton-motive force.

The Biological Nitrogen Cycle

Nitrogen, an essential element for life, is present in proteins, nucleic acids and many biomolecules. In nature, nitrogen is distributed between three major pools, atmosphere, soil/groundwater and biomass, with oxidation states ranging from +5 in the most oxidized compound (nitrate) to −3 in the most reduced form (ammonia/ammonium). Ammonia (NH₃) predominates at alkaline pH whereas the protonated ionic form, ammonium (NH₄⁺), prevails at neutral and acidic conditions. Interconversions of different N-compounds allow a complex nitrogen exchange in the ecosystems that constitutes the so-called nitrogen cycle (Fig. 1), with prokaryotes playing a predominant role. Biological N-cycle includes redox reactions catalyzed by enzymes with different metal cofactors (Table 1), but global N-cycle also includes abiotic processes like atmospheric N-oxide production by lightning and photochemical reactions.

Microbes may use the N-cycle reactions for assimilatory or respiratory/dissimilatory purposes. Assimilatory processes allow nitrogen incorporation into cell material (Fig. 2). Ammonium, the preferred N-source for microbial growth, is directly assimilated forming glutamine and glutamate, but nitrate assimilation in plants and microorganisms occurs through two sequential reductive reactions (NO₃[−] → NO₂[−] → NH₄⁺) catalyzed by assimilatory nitrate and nitrite reductases. Dinitrogen constitutes about 78% of the atmosphere, but only a few free-living or symbiotic N₂-fixing prokaryotes may convert this stable molecule into ammonium through a high energy-consuming reaction catalyzed by nitrogenase.

Microbes also transform N-compounds by respiratory processes for energy conservation or by dissimilatory reactions used for redox balancing or N-detoxification (Fig. 3). Nitrification consists in two separate steps, ammonia oxidation to nitrite (NH₃ → NH₂OH → NO₂[−]) performed by ammonia-oxidizing bacteria/archaea (AOB/AOA) and nitrite oxidation to nitrate (NO₂[−] → NO₃[−]) carried out by nitrite-oxidizing bacteria (NOB), although some strains fulfill complete oxidation of ammonia to nitrate (comammox). Denitrification is the sequential reduction of nitrate to dinitrogen (NO₃[−] → NO₂[−] → NO → N₂O → N₂) coupled to proton-motive force (pmf) generation. This allows some prokaryotes to grow anaerobically using these compounds as electron acceptors, although also exist aerobic denitrifiers. Anaerobic ammonium oxidation (anammox) is performed by some planctomycetes that generate dinitrogen

[☆]Change History: May 2019. Purificación Cabello, Víctor M. Luque-Almagro, María D. Roldán and Conrado Moreno-Vivián updated the text, references and figures. This is an update of Cabello, P., Roldán, M.D., Castillo, F., Moreno-Vivián, C., 2009. Nitrogen cycle. In: Schaechter, M. (Ed.), *Encyclopedia of Microbiology*, third ed. Academic Press, pp. 299–321.

This article is an update of P. Cabello, M.D. Roldán, F. Castillo, C. Moreno-Vivián, Nitrogen Cycle, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 299–321.

Fig. 1 Overview of the biological nitrogen cycle. The different N-compounds are arranged according to the N-oxidation state. Main oxidative or reductive N-cycle pathways (indicated by arrows), and their corresponding enzymes are shown with different colors. Anaerobic ammonia oxidation (anammox), dissimilatory nitrate reduction to ammonia (DNRA) and complete ammonia oxidation to nitrate (comammox) are indicated by dotted, dashed and dotted/dashed arrows, respectively. Anaerobic processes and oxygen-sensitive reactions are drawn in the left, and aerobic processes are shown in the right.

coupling ammonium oxidation to nitrite reduction ($\text{NH}_4^+ + \text{NO}_2^- \rightarrow \text{N}_2$). The combined action of nitrification, denitrification and anammox causes losses of fixed nitrogen from environments; by contrast assimilatory pathways make nitrogen available for organisms. Finally, different enzymes and pathways are involved in detoxification of harmful N-compounds like nitrite, nitric oxide, hydroxylamine and hydrazine.

In last decades, human activities have altered drastically the natural balance of the N-cycle. Annually, huge amounts of N-compounds enter in the ecosystems by anthropogenic processes such as production of synthetic fertilizers by the Haber-Bosch process and release of N-oxides by fossil fuel combustion.

Ammonium Assimilation

Ammonium assimilation requires the active transport of this ion through Amt permeases and its further incorporation into C-skeletons by the glutamine synthetase-glutamate synthase pathway or the glutamate dehydrogenase enzyme (Table 1). Once glutamine and glutamate are formed, other organic N-compounds are synthesized by a set of secondary N-transfer reactions (Fig. 2).

Glutamine synthetase (GS) catalyzes the ATP-dependent synthesis of glutamine from glutamate and ammonium. In most bacteria and archaea, GS is a dodecameric protein (*glnA* gene product) arranged in two hexagonal rings with a cylindrical aqueous channel, although octameric or hexameric isoenzymes are present in some bacteria. Glutamate synthase (glutamine:2-oxoglutarate amidotransferase, GOGAT) is an iron-sulfur flavoprotein that catalyzes the reductive transfer of the glutamine amide group to 2-oxoglutarate, yielding two molecules of glutamate. NADPH-GOGAT of heterotrophic bacteria is arranged in $\alpha_4\beta_4$ structure with one [3Fe-4S] center and FMN bound to α subunits (*gltB* gene product), FAD bound to β subunits (*gltA* gene product) and two additional [4Fe-4S] centers located in the subunit interface. Cyanobacteria may contain a dimeric NADH-GOGAT or a monomeric ferredoxin-GOGAT, which is similar to the large subunit of NADPH-GOGAT. Glutamate dehydrogenase (GDH) usually catalyzes the oxidative deamination of glutamate, but at high ammonium concentrations (mM) it may promote the reductive incorporation of ammonium to 2-oxoglutarate, acting as an alternative pathway for ammonium assimilation.

Table 1 Structure and cofactors of the main prokaryotic enzymes involved in the processes of the nitrogen cycle

Processes and enzymes	Enzyme structure (frequent protein name)	Subunit molecular mass (kDa)	Cofactors	Subcellular location	Relevant organisms
Ammonium assimilation					
Glutamine synthetase					
GSI	Dodecamer (GlnA)	50	Mg ²⁺	Cytoplasm	Heterotrophic bacteria, cyanobacteria, phototrophic bacteria, archaea
GSII	Octamer	45–50	Mg ²⁺	Cytoplasm	<i>Rhizobium</i> , <i>Frankia</i> , <i>Streptomyces</i>
GSIII	Hexamer	80	Mg ²⁺	Cytoplasm	<i>Bacteroides</i> , <i>Butyrivibrio</i> , cyanobacteria
Glutamate synthase					
NADPH-GOGAT	Octamer $\alpha_4\beta_4$ (GltBA)	150 (α , GltB) 50 (β , GltA)	FMN, [3Fe4S] FAD, 2x[4Fe4S]	Cytoplasm	Most bacteria. Archaea have truncated forms (α - or β -like subunits)
Ferredoxin-GOGAT	Monomer	170	FMN, [3Fe4S]	Cytoplasm	Cyanobacteria
Glutamate dehydrogenase					
GDH1, GDH2	Hexamer	45–55	NAD or NADP	Cytoplasm	Most bacteria and archaea
Nitrogen fixation					
Mo-nitrogenase	MoFe-protein (NifDK): Heterotetramer $\alpha_2\beta_2$ Fe-protein (NifH): Dimer	55–60 (α, β) 64	2xFeMoCo (MoFe ₇ S ₉ C), 2xP-clusters (Fe ₈ S ₇) [4Fe-4S]	Cytoplasm	<i>Klebsiella</i> , <i>Azotobacter</i> , <i>Clostridium</i> , <i>Rhizobium</i> , <i>Frankia</i> , <i>Rhodobacter</i> , cyanobacteria, methanogenic archaea
V-nitrogenase	VFe-protein (VnfDKG): $\alpha_2\beta_2\delta_2$ Fe-protein (VnfH): dimer	55–60 (α, β); 15 (δ) 64	2xFeVCo, 2xP-clusters [4Fe-4S]	Cytoplasm	<i>Azotobacter chroococcum</i> , <i>Azotobacter vinelandii</i>
Fe-nitrogenase	FeFe-protein (AnfDKG): $\alpha_2\beta_2\delta_2$ Fe-protein (AnfH): dimer	55–60 (α, β); 15 (δ) 64	2xFeFeCo, 2xP-clusters [4Fe-4S]	Cytoplasm	<i>Rhodobacter capsulatus</i> , <i>Azotobacter vinelandii</i>
Nitrate assimilation					
Nitrate reductase					
NADH-Nas	Heterodimer (Nas)	90–95 (catalytic) 45 (diaphorase)	[4Fe4S], MGD FAD	Cytoplasm	<i>Klebsiella</i> , <i>Bacillus subtilis</i> , <i>Rhodobacter capsulatus</i> , <i>Paracoccus denitrificans</i>
Ferredoxin-Nas	Monomer	80–105	[4Fe4S], MGD	Cytoplasm	Cyanobacteria, <i>A. vinelandii</i> , <i>Haloferax mediterranei</i> (105- and 50-kDa dimer)
Nitrite reductase					
NADH-Nir	Heterodimer	87 (catalytic) 12 (NirD)	FAD, [4Fe4S], siroheme	Cytoplasm	<i>Klebsiella</i> , <i>Bacillus subtilis</i> , <i>Rhodobacter capsulatus</i> , <i>Paracoccus denitrificans</i>
Ferredoxin-Nir	Monomer	55–66	[4Fe4S], siroheme	Cytoplasm	Cyanobacteria, <i>Haloferax mediterranei</i>
Nitrification					
Ammonia monooxygenase (Amo)	Heterotrimer (AmoABC)	27 (AmoA) 38 (AmoB) 32 (AmoC)	Cu, Fe	Cytoplasmic membrane	AOB (<i>Nitrosomonas</i>) and AOM. Some <i>Nitrospira</i> strains (comammox) with a different AmoA subunit
Hydroxylamine oxidoreductase (Hao)	Homotrimer	63	8xheme <i>c</i>	Periplasm	<i>Nitrosomonas</i> and AOB. In <i>Paracoccus</i> is a 20-kDa monomer with non-heme iron
Nitrite oxidoreductase (Nxr)	Heterodimer (NxrAB) Heterotetramer (NxrABIC)	115 (NxrA) 65 (NxrB)	MGD, FeS FeS heme <i>b</i> (NxrI) and <i>c</i> (NxrC)	Membrane (nNxr, active site facing cytoplasm; pNxr, active site outside)	<i>Nitrobacter</i> (nNxr), <i>Nitrospira</i> (pNxr), anammox bacteria (<i>Kuenenia</i>)

(Continued)

GS, the primary ammonium-assimilating enzyme, is target of a complex regulation at both transcriptional (*glnA* gene expression) and post-translational (GS activity) levels. In enterobacteria, GS activity is regulated by reversible adenylation/deadenylation of a tyrosine residue of each subunit. Thus, under N-starvation (high 2-oxoglutarate; low glutamine) deadenylylated GS is fully active whereas under N-excess (low 2-oxoglutarate; high glutamine) GS is adenylylated to decrease its activity. The GS adenylation state is controlled by the trimeric PII protein (GlnB), a 2-oxoglutarate sensor that is uridylylated/deuridylylated by an uridylyltransferase/uridylyl-removing bifunctional enzyme. Unmodified GlnB stimulates GS adenylation (inactivation) whereas uridylylated GlnB promotes GS deadenylation (activation). Additionally, *glnA* gene expression is controlled by the two-component general nitrogen regulatory system Ntr. At low nitrogen, the NtrB sensor phosphorylates an aspartic residue of NtrC, and phosphorylated NtrC activates transcription of *glnA* and other N-regulated genes, which are recognized by the RNA polymerase σ^{54} factor (RpoN). At high nitrogen, deuridylylated GlnB promotes NtrC dephosphorylation through NtrB, decreasing transcription of *glnA* and N-regulated genes.

This regulation model for ammonium assimilation is widely distributed among bacteria, although some bacteria lack Ntr system. In cyanobacteria the main nitrogen regulator is NtcA, a CRP-family transcription factor. NtcA activates *amt1* (ammonium permease) and *glnA* (GS), but represses the *gifAB* genes encoding small polypeptides of 7- and 17-kDa (IF7 and IF17) that inactivate GS under N-excess. Therefore, GS is not adenylylated but controlled by inactivating factors IF7/IF17. In addition, PII protein is phosphorylated rather than modified by uridylylation. Both PII and NtcA proteins bind 2-oxoglutarate, and their signaling and transcriptional activities seem to be mutually dependent.

Fig. 2 Assimilatory N-cycle processes. Microbes may use different N-sources for growth, including both organic and inorganic N-compounds. In organic compounds, nitrogen is usually found in its fully reduced state, and therefore, ammonium assimilation only requires the transport of this ion inside the cells (Amt transporter) and its further incorporation into C-skeletons either by the glutamine synthetase-glutamate synthase (GS-GOGAT) pathway or the glutamate dehydrogenase (GDH) enzyme. Assimilation of oxidized N-compounds (nitrate, nitrite) requires the specific oxyanion uptake by ATP- or pmf-dependent transporters and their reduction by the Mo-containing nitrate reductase (Nas) and the siroheme-containing nitrite reductase (siroheme-Nir). These assimilatory enzymes use either NADH or reduced ferredoxin (Fd_{red}) as electron donor. In N_2 -fixing bacteria and archaea, dinitrogen gas is reduced to ammonium by the enzyme nitrogenase (N_2ase). Ammonium formed by nitrate/nitrite reduction or nitrogen fixation is mainly incorporated into cell material by the GS-GOGAT pathway. 2OG, 2-oxoglutarate.

Fig. 3 Respiratory and dissimilatory N-cycle processes. Substrates, intermediates, products and enzymes of denitrification, nitrification, complete ammonia oxidation to nitrate (comammox), nitrifier denitrification, anaerobic ammonia oxidation (anammox) and dissimilatory nitrate reduction to ammonia (DNRA) are indicated. These processes are boxed in different colors.

Nitrogen Fixation

Biological nitrogen fixation is only performed by some bacteria and archaea, but provides a major source of available (fixed) nitrogen for organisms in both terrestrial and marine environments. Nitrogenase catalyzes the six-electron reduction of dinitrogen to ammonium, with a high consumption of ATP, and also forming H_2 during the process:

Prokaryotes may fix dinitrogen either free-living or in symbioses or associations with plants. Free-living diazotrophs may grow under anaerobic, microaerobic or aerobic conditions, but in this case, as nitrogenase is oxygen-labile, different mechanisms are used to protect the enzyme against oxygen. In the most representative *Rhizobium*-legume symbiosis, N_2 -fixation occurs inside plant root nodules, specialized structures that allow bacterial growth under microaerobiosis. Actinobacteria (*Frankia*) establish symbioses with non-leguminous trees and cyanobacteria (*Nostoc*) with bryophytes, pteridophytes and angiosperms (*Gunnera*). Some crops also obtain part of their N-demand by association with N_2 -fixing proteobacteria in the root surface (*Azospirillum*) or that colonize plant tissues as endophytes (*Azoarcus*, *Herbaspirillum*)

Three types of nitrogenases containing molybdenum, vanadium or iron are known (Table 1). Mo-nitrogenase, the main enzyme, consists of a catalytic MoFe-protein (dinitrogenase) and an electron transfer Fe-protein (dinitrogenase reductase), which binds ATP and also participates in MoFe-protein maturation. The $\alpha_2\beta_2$ tetrameric MoFe-protein (encoded by *nifDK* genes) contains 2 Mo, 30 Fe and 32 S atoms arranged in two pairs of special metallocenters, FeMo-cofactor and P-cluster. The FeMo-cofactors, composed of $MoFe_7S_9C$ -homocitrate, are bound to the α -subunits and the P-clusters, composed of Fe_8S_7 ([4Fe-4S] and [4Fe-3S] centers sharing one S), are located at the α/β -subunit interfaces. The homodimeric Fe-protein (*nifH* gene product) has a single [4Fe-4S] center bridging both subunits. The catalytic mechanism involves a Fe-protein cycle consisting in complex formation, electron transfer to MoFe-protein, ATP hydrolysis and reduction of the oxidized Fe-protein with the physiological donor (ferredoxin or flavodoxin), and a MoFe-protein cycle that includes the reactions within the MoFe-protein for substrate reduction.

Nitrogen fixation is regulated at transcriptional and post-translational levels in response to ammonium and oxygen, although different regulatory mechanisms are involved depending on the organism. In *Klebsiella*, *nif* gene expression is controlled by the regulatory *nifLA* genes, which respond to the general Ntr system. NifA is a σ^{54} -dependent transcriptional activator and Nifl is a flavoprotein that inactivates NifA in response to oxygen. In anoxygenic phototrophic bacteria, post-translational regulation of nitrogenase allows a rapid response to O_2 and NH_4^+ (switch-off/switch-on) through reversible ADP-ribosylation of Fe-protein by the DraT/DraG system, which in turn, is regulated by PII protein. In response to ammonium, DraT catalyzes the transference of ADP-ribose from NAD^+ to a Fe-protein subunit, preventing nitrogenase complex formation and leading to enzyme inactivation. At low ammonium, DraG removes the ADP-ribose group to activate nitrogenase.

Establishment of legume-rhizobia symbiosis requires the formation of a specialized organ, the nodule, where N_2 -fixation occurs. Nodulation is a specific interaction in which a rhizobial strain infects a defined plant-host, with a close bacteria-plant coordination based on exchange of diffusible signal molecules. Plant-secreted flavonoids act as specific signals recognized by compatible bacterial strains, which respond by attaching to root-hairs and inducing nodulating (*nod*) genes that activate infection events. Cortical cell divisions generate the nodule primordium and bacteria enter the plant through an intracellular tubular structure, the infection thread, which grows and ramifies into the nodule primordium. Bacteria released into the cells are enclosed in the symbiosome, a compartment where they differentiate into N_2 -fixing bacteroids. The nodules maintain low oxygen levels to avoid nitrogenase inhibition, and leghemoglobin plays an important role as O_2 -scavenger. Bacteroids use dicarboxylic acids supplied by the plant to generate ATP and reducing power for N_2 -fixation, and ammonia formed is assimilated in host cells by the GS-GOGAT pathway. Fixed nitrogen is exported through the xylem from nodules to the rest of the plant, either as amides (asparagine) or ureides (allantoin or allantoic acid).

Nitrate Assimilation

Higher plants, fungi, algae, archaea and bacteria may use nitrate as N-source for growth by a process that requires the transport of nitrate inside the cells and its further reduction to ammonium, which is incorporated into C-skeletons by GS-GOGAT. Assimilatory nitrate and nitrite reductases use either NADH or reduced ferredoxin as electron donor (Fig. 2, Table 1). Nitrate uptake may occur either by ATP-dependent ABC transporters that include a periplasmic substrate-binding protein, a homodimeric transmembrane protein and a homodimeric or heterodimeric cytoplasmic ATPase, or by pmf-dependent MSF permeases that act as H^+/NO_3^- symporters.

Prokaryotic nitrate reductases are metalloenzymes with a Mo-bis-molybdopterin guanine dinucleotide (Mo-bis-MGD) cofactor that catalyze the two-electron reduction of nitrate to nitrite, although cytoplasmic assimilatory nitrate reductases (Nas) are structurally and functionally different from the periplasmic (Nap) or membrane-bound (Nar) enzymes involved in dissimilatory/respiratory processes. Ferredoxin-dependent nitrate reductases are monomeric proteins that contain a [4Fe-4S] center and Mo-bis-MGD, but NADH-dependent Nas require an additional FAD-containing oxidoreductase that mediates electron transfer from NADH to the catalytic Mo-containing subunit. Assimilatory nitrite reductases catalyze the six-electron reduction of nitrite to ammonium and contain an iron-sulfur center and siroheme, a special porphyrin with eight carboxylic acid peripheral sidechains,

but NADH-dependent nitrite reductases also contain FAD. They are also completely different in structure and function to the cytochrome *cd₁* (NirS) or copper (NirK) nitrite reductases involved in denitrification, or the dissimilatory pentaheme NrfA enzyme of some bacteria.

In *Paracoccus denitrificans*, the nitrate reductase catalytic subunit (NasC), the FAD-containing nitrite reductase (NasB) and a Rieske-type protein with a [2Fe-2S] cluster (NasG) form a functional NasBGC complex in which NasG mediates electron transfer from an unique NADH-binding site present in NasB to the nitrate and nitrite reduction sites located in NasC and NasB, respectively. Phylogenetical analyses suggest that a composite nitrate/nitrite reductase system similar to the NasBGC complex is widespread among bacteria.

Nitrate assimilation is usually regulated by nitrate induction (pathway-specific control) and ammonium repression (general N-control), but significant differences exist depending on the organism. In cyanobacteria, N-control is exerted by the NtcA transcription factor, which is influenced by the 2-oxoglutarate PII sensor, and the specific positive control by nitrate involves the LysR-family NtcB protein and other regulators. In *Klebsiella*, ammonium control is mediated by the NtrBC system, whereas nitrate induction requires the transcription antitermination protein NasR. Under N-limitation the Ntr system activates *nas* gene expression, but without nitrate transcription terminates prematurely. However, in presence of nitrate, NasR acts as transcription antiterminator binding to mRNA and allowing *nas* gene expression. In other bacteria nitrate control requires a two-component system composed of a nitrate sensor (NasS) and a response regulator (NasT), which also acts as transcriptional antiterminator. In *Paracoccus denitrificans*, ammonium and nitrate exert a complex control involving both transcriptional and translational mechanisms through the NtrBC and NasTS systems. The *nas* genes are transcribed and translated only when nitrate is present, and ammonium absent. In presence of ammonium the genes are not transcribed, and in absence of ammonium and nitrate the genes are transcribed but not translated.

Nitrification

Classical nitrification consists on the aerobic oxidation of ammonium to nitrate in two separate steps, the oxidation of ammonium to nitrite via hydroxylamine and the subsequent oxidation of nitrite to nitrate, carried out by ammonia-oxidizing bacteria (AOB) and nitrite-oxidizing bacteria (NOB), respectively (Fig. 3). These chemolithoautotrophic bacteria (represented by *Nitrosomonas* and *Nitrobacter* species) use energy released in ammonia or nitrite oxidation to support CO₂ fixation and growth. Electron transfer to oxygen generates an electrochemical gradient that drives ATP synthesis and NAD reduction by reverse electron transport. Different ammonia-oxidizing archaea (AOA) have been also described, in addition to *Rhodospseudomonas* and *Thiocapsa* strains that use nitrite oxidation for supporting anoxygenic photosynthesis, and heterotrophic and methanotrophic bacteria that oxidize ammonia without gaining energy for growth. Cross-feeding interactions and co-aggregation of AOB/AOA and NOB is frequently observed. Thus, reciprocal feeding allows the use of cyanate as nitrification substrate since NOB have a cyanase that converts cyanate into CO₂ and ammonia, which is oxidized by AOB to form nitrite used by NOB. However, until the very recent discovery of some *Nitrospira* strains that perform complete ammonia oxidation to nitrate by the so-called comammox process, all known nitrifiers were unable to fulfill both nitrification steps despite complete nitrification is energetically advantageous.

In *Nitrosomonas* and other AOB, ammonia is first oxidized to hydroxylamine by ammonia monooxygenase, a multimeric transmembrane complex (AmoABC) with Cu and non-heme iron. Hydroxylamine is further converted to nitrite by Hao, a periplasmic trimeric octaheme *c* hydroxylamine oxidoreductase (Table 1). Electrons are passed to the quinol pool through cytochrome *c₅₅₄* and a NapC-family membrane-anchored *c*-type cytochrome. Ubiquinol is oxidized by the cytochrome *bc₁* complex, which transfers electrons to oxygen via an *aa₃*-type oxidase generating pmf, and by an NADH-ubiquinone oxidoreductase that generates NADH through reverse electron transfer. Ammonia-oxidizing archaea (AOA) contain *amo*-like genes but lack hydroxylamine oxidation/detoxification genes, suggesting a different mechanism for archaeal ammonia oxidation. Instead of hydroxylamine, archaeal Amo may produce nitroxyl (HNO), which is oxidized to nitrite by a putative nitroxyl oxidoreductase.

Nitrite oxidation in NOB requires a multimeric membrane-bound nitrite oxidoreductase (Nxr) with Mo-*bis*-MGD, iron-sulfur centers and heme groups. The Mo-containing catalytic subunit may have a periplasmic location (pNxr), contributing to pmf generation directly, or faces the cytoplasm and electrons from nitrite oxidation flow to an electrogenic *aa₃*-type cytochrome oxidase (nNxr). Both types of Nxr evolved independently (*Nitrospira* pNxr is related to DMSO reductases whereas *Nitrobacter* nNxr is similar to Nar) and were probably spread among NOB by lateral gene transfer.

Nitrite-oxidizers can be involved in complex associations with different microorganisms. NOB diversity was also revealed by the unexpected discovery of *Nitrospira* strains that perform complete ammonia oxidation to nitrate (comammox) using an ammonia monooxygenase with an AmoA subunit different from those of AOB/AOA. Therefore, identification of *Nitrospira*-like *amoA* genes provides evidence of comammox. Metagenomic analysis reveals that comammox is widespread in natural ecosystems and wastewater treatment plants sludge.

Denitrification

In denitrification, nitrate, nitrite and gaseous nitric and nitrous oxides are used as terminal electron acceptors for anaerobic respiration, generating dinitrogen as final product. This four-step pathway is sequentially catalyzed by the enzymes nitrate, nitrite,

nitric oxide and nitrous oxide reductases (Fig. 3, Table 1). Many bacteria and archaea denitrify under oxygen-limited conditions, but some organisms also perform aerobic denitrification. Other microbes are not considered true denitrifiers because they develop an incomplete process, releasing nitrite or emitting N_2O to the atmosphere.

Nitrate reduction, the first denitrification step, is catalyzed by membrane-bound respiratory (Nar) or periplasmic (Nap) nitrate reductases. Most bacterial Nar are heteromeric complexes including a catalytic protein with Mo-*bis*-MGD and one [4Fe-4S] cluster (NarG), an electron transfer protein with one [3Fe-4S] and three [4Fe-4S] centers (NarH), and a quinol-oxidizing dihem *b* membrane protein (NarI). In these systems (known as nNar) the NarG active site faces the cytoplasm and electrons pass from the membrane quinol pool to nitrate via NarI heme groups and NarH iron-sulfur clusters allowing pmf generation by a redox loop mechanism. Therefore, nitrate must be incorporated inside the cells whereas nitrite needs to be exported to the periplasm. The *Paracoccus denitrificans* narK gene encodes a transmembrane protein with a NarK1 domain that functions as NO_3^-/H^+ symporter to initiate respiration and a NarK2 domain acting as NO_3^-/NO_2^- antiporter. In archaea exists a similar nNar with the active site in the cytoplasm and a pNar with the active site located outside the membrane, coupled to a quinone-cycle for energy-conservation through dihem (NarC) and Rieske-type (NarB) proteins.

Periplasmic nitrate reductases were initially described in phototrophic and denitrifying bacteria, but they are widespread among proteobacteria. The Nap system is usually composed of a large catalytic subunit containing [4Fe-4S] and Mo-*bis*-MGD (NapA) that receives electrons from a dihem-*c* cytochrome (NapB). A quinol-oxidizing, membrane-anchored tetraheme-*c* protein (NapC) donates electrons to NapB, but some bacteria lack NapB or NapC and/or include a quinol-oxidizing iron-sulfur NapGH complex. In addition, NapF participates in the assembly of the [4Fe-4S] center into NapA, and NapD is involved in NapA maturation. Aerobic denitrifiers couple Nap enzyme to nitrite and N-oxide reductases, but besides of its role in denitrification, Nap also functions in redox balancing (dissipation excess reducing power).

Nitrite reductases involved in denitrification are periplasmic enzymes that catalyze the one-electron reduction of NO_2^- to NO. There are two types of denitrifying nitrite reductases, the homodimeric containing *c*-type (electron entry site) and *d*₁-type (catalytic site) heme groups, and the trimeric Cu-NirK which includes a type-I Cu site that mediates electron transfer to a catalytic type-II Cu. Both enzymes receive electrons from periplasmic *c*-type cytochromes or cupredoxins that are connected with the cytochrome *bc*₁ complex, making electron transfer from quinones to nitrite electrogenic. It was believed that denitrifying bacteria contain either NirS or NirK, but denitrifiers with both enzymes have been recently described.

Membrane-bound nitric oxide reductases catalyze the reduction of NO to N_2O . Most denitrifying bacteria have a heteromeric NO reductase (cNor) constituted by a small heme *c*-containing subunit (NorC) and a catalytic subunit (NorB) that binds heme *b* and a dinuclear heme *b*₃ and non-heme iron (Fe_B) center. Electrons from pseudoazurin or *c*-type cytochrome pass to heme *c* (NorC) and then to *b*-heme groups and Fe_B (NorB), where NO is reduced to N_2O . Some bacteria have a quinol-dependent monomeric enzyme (qNor) that contains only the dinuclear center (heme *b* and Fe_B). *Bacillus azotoformans* possesses an unusual Cu_A-containing dimeric variant (Cu_AqNor) that uses menaquinol or cytochrome *c* as reductant.

Reduction of N_2O to N_2 is catalyzed by a periplasmic homodimeric nitrous oxide reductase (NosZ) with two copper centers, a catalytic tetranuclear Cu_Z and a dinuclear Cu_A that contributes to enzyme stabilization and receives two-electrons from cytochrome *bc*₁ via cytochrome *c* or cupredoxin. Many non-denitrifying N_2O -reducing bacteria and archaea act as real N_2O sinks since they do not generate, but remove, this greenhouse gas. Genome sequencing reveals that NosZ from these organisms usually belongs to clade II, a phylogeny lineage distinct from NosZ of typical denitrifying bacteria (clade I). Clade II proteins are translocated to the periplasm by the Sec pathway whereas most clade I NosZ contain the twin-arginine motif for the Tat pathway. The *Wolinella succinogenes* NosZ (clade II) includes an additional monoheme-*c* domain that receives electrons from menaquinol through the membrane iron-sulfur proteins NosGH.

A proteomic-based interactomic approach in *Pseudomonas aeruginosa* revealed that all denitrification enzymes (NarGHI/NirS/NorBC/NosZ), nitrate transporter (NarK2) and regulatory or enzyme maturation proteins (NarXL, NirFMN, NosFL) form a functional membrane-attached supercomplex that interacts with NADH dehydrogenase, ATPase, TCA cycle enzymes, Sec-translocon components, and flagella-assembly proteins. This dynamic supercomplex probably optimizes electron transfer and energy conservation, reducing reactive oxygen species formation.

Denitrification is controlled by multiple regulatory systems that basically respond to oxygen, nitrate/nitrite and N-oxides, but showing differences among microorganisms. These regulators include FNR/CRP-superfamily oxygen (FNR, ANR), nitrate (NarR) and nitric oxide (NNR, DNR) sensors, oxygen-responsive (FixLJ, ArcAB) or nitrate-responsive (NarXL, NarQP) two-component systems, and NO-sensing Fe-S flavoproteins (NosR, NirI), non-heme iron σ^{54} -transcriptional activators (NorR) or Rrf-family transcriptional repressors (NsrR).

Considering that nitrite is an intermediate of both nitrification and denitrification, ammonia oxidation to nitrite may be coupled to denitrification in the so-called nitrifier denitrification, which allows AOB to detoxify nitrite accumulated during nitrification (Fig. 3). Under oxygen-limitation AOB oxidize ammonia to nitrite via hydroxylamine, and nitrite is further reduced to N_2O or dinitrogen by denitrification enzymes ($NH_3 \rightarrow NH_2OH \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$). Ammonia-oxidizing archaea (AOA) also perform nitrifier denitrification, but they could generate N_2O by a different mechanism (via HNO instead of NH_2OH). When nitrifiers and denitrifiers are present in the same environment, nitrification and denitrification can be coupled to remove both ammonia and nitrate ($NH_3 \rightarrow NH_2OH \rightarrow NO_2^- \rightarrow NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$). On the other hand, heterotrophic nitrification may occur in some denitrifiers like *Paracoccus denitrificans*, where a hydroxylamine oxidoreductase with non-heme iron catalyzes oxidation of hydroxylamine to nitroxyl radicals that dimerize to form N_2O (under anoxia) or react with oxygen forming nitrite (in aerobiosis). Methane oxidation coupled to denitrification has been also described. Metagenomic sequencing has revealed

that some denitrifying methanotrophs form N_2 without N_2O synthesis because a putative NO dismutase catalyzes the direct conversion of NO into N_2 generating oxygen ($2NO \rightarrow N_2 + O_2$) that supports methane oxidation.

Anaerobic Ammonium Oxidation

Anaerobic ammonium oxidation to dinitrogen with nitrite as electron acceptor (anammox) allows some chemolithoautotrophic bacteria (Planctomycetes) to grow using the exergonic reaction $NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O$ as primary source of energy (Fig. 3). Metagenomic studies have revealed that anammox bacteria significantly contribute to removal of fixed nitrogen in oceans, terrestrial environments and wastewater treatment plants. Genomics also provided information about the anammox pathway, which proceeds in three steps that generate two highly toxic intermediates, NO and hydrazine (N_2H_4). First, nitrite is reduced to NO by *cd₁-NirS* (*Kuenenia*, *Scalindua*), Cu-NirK (*Jettenia*) or a novel Hao-like nitrite reductase (*Brocadia*). Then, a heterotrimeric heme *c*-containing hydrazine synthase (Hzs) combines NO and ammonia to form hydrazine, which is finally oxidized to N_2 by a homotrimeric octaheme-*c* hydrazine dehydrogenase (Hdh) homologous to Hao of AOB (Table 1). Anammox bacteria have special ladderane lipids that confer impermeability and rigidity to the membranes of the anammoxosome, a compartment that internalizes the anammox enzymes reducing hydrazine losses. The four electrons released in the Hdh reaction are transferred to the proton-pumping cytochrome *bc₁*, yielding energy. Cytochrome *c* donates the three electrons required for the Hzs reaction and the single electron consumed in nitrite reduction. In addition, anaerobic oxidation of nitrite to nitrate by a Nxr-like nitrite oxidoreductase provides electrons required for C-fixation by the acetyl-CoA pathway. Anammox substrates are also formed by an Nrf-type nitrite reductase, which converts nitrite into ammonium, and a Hao-family multiheme hydroxylamine oxidase, which synthesizes NO from hydroxylamine.

Other Processes of the N-Cycle

Nitrogen mineralization is the process by which inorganic nitrogen is obtained by decomposition of organic N-compounds. Extracellular proteolytic enzymes of saprophytic bacteria and fungi are responsible for protein degradation to small peptides and amino acids, which are finally degraded releasing ammonium. Therefore, this process is also known as ammonification, although this term is used as well for other N-cycle ammonium-generating processes.

Dissimilatory nitrate reduction to ammonium (DNRA), or nitrate ammonification, is an anaerobic process in which nitrate reduction to nitrite by Nar or Nap enzymes is followed by the dissimilatory six-electron reduction of nitrite to ammonium catalyzed by a periplasmic pentaheme cytochrome *c* nitrite reductase (NrfA), which receives electrons from a membrane NapC-family cytochrome (NrfH) or a menaquinol-oxidizing complex (NrfBCB), or by a cytoplasmic NADH-dependent, siroheme-containing nitrite reductase (Table 1). The role of these enzymes is to detoxify nitrite formed in nitrate respiration rather than to generate ammonium for N-assimilation.

Many N-compounds are toxic for organisms. Therefore, a number of enzymes play a role in detoxification of these harmful molecules. Some of these enzymes detoxify NO by its oxidation to nitrate (flavohemoglobin Hmp) or its reduction either to N_2O (Nor, flavorubredoxin, and flavo-diiron proteins) or ammonium (nitrite reductase NrfA). Hydroxylamine detoxification is also achieved by reduction to ammonium (*cd₁-Nir*, NrfA) or oxidation to nitrite (Hao).

Environmental Aspects of N-Cycle, Human Impact and Perspectives

Human impact affects the N-cycle at global scale, with relevant environmental, agronomic and health implications. Actually, over half of the N-fixed that enters in ecosystems has anthropogenic origin, and human activities also modify composition and dynamics of microbial populations in terrestrial, freshwater and marine environments. The excessive use of synthetic fertilizers in agricultural practices leads to accumulation of nitrate and nitrite in groundwater causing eutrophication of aquatic ecosystems and human health risks, since consumption of drinking water with high nitrate may produce methaemoglobinemia and gastric cancer. Fossil fuel combustion is also the major source of N-oxide emissions that contribute to global warming and other environmental hazards. Thus, N_2O is a stable gas with about 300-fold more greenhouse effect than CO_2 and also participates in photochemical reactions that destroy the stratospheric ozone layer. In addition, atmospheric NO may be oxidized to nitrogen dioxide (NO_2), which after hydration generates HNO_3 causing acid rain. Symbiotic nitrogen fixation provides a source of fixed N for plant growth without the need for fertilizers. Establishment of artificial symbiosis or associations between diazotrophic organisms and agronomic plants, or potential transfer of N_2 -fixing capacity to mayor crops, could reduce the demand for chemical fertilizers. Nitrification, denitrification and anammox are the main pathways for N-losses in natural ecosystems and wastewater treatment plants, but these processes have also negative effects since significantly contribute to N_2O emissions. A better understanding of the major N-cycle processes and their relative contribution as N_2O sources or sinks will enable to improve ecosystem management and to develop tools for mitigation the negative effects of anthropogenic N-inputs.

Understanding of the role of microbial populations and consortia in N-cycle was limited by the fact that vast majority of bacteria present in an ecosystem are non-cultivable by traditional microbiology techniques. However, modern genomics and metagenomics

tools are changing our knowledge of these communities in natural habitats and their impacts on N-cycle. Comparative genomics reveals important networks of microbial populations, contributing to the identification of novel protein functions and metabolisms, and bringing to light that diversity of microorganisms involved in N-cycle and variety of their functions are much higher than previously thought. Thus, omic-based approaches have changed our view of N-cycle with the elucidation of the anammox pathway and the discovery of new processes like comammox, nitrifier denitrification and methane oxidation coupled to denitrification, among others.

Genome-resolved information allows the elaboration of new concepts on the biochemical origin of biological diversity, shifting our traditional knowledge based on particular processes and organisms (i.e., diazotrophs, nitrifiers, denitrifiers) into a global view that integrates the distinct gene/protein modules for microbial adaptation or survival in different environments. This emerging view emphasizes the importance of microbial interactions, metabolic by-products exchange and symbioses, and provides new inputs to translate this information into useful models for understanding global changes and predicting N-cycle fluxes to mitigate greenhouse gas emissions.

No Bones About It: The Bacterial Cytoskeleton

William Margolin, McGovern Medical School, Houston, TX, United States

© 2019 Elsevier Inc. All rights reserved.

Glossary

Cytokinesis Splitting of the cytoplasm of a mother cell into multiple daughter cells.

Cytoskeleton A subcellular structure composed of assembled proteins that is important for organization of cellular components.

DAPI 4',6-diamidino-2-phenylindole, a fluorescent dye that binds to DNA, excited by UV light and emitting in the blue wavelengths.

Immunofluorescence Fixed cells are incubated with a primary antibody against a protein, then a secondary antibody with a fluorescent tag that binds the primary antibody, which results in a fluorescent signal reflecting the location of the protein.

Immunogold Like immunofluorescence, except that the secondary reagents are nanometer-sized gold particles, which can only be observed with transmission electron microscopy.

Nucleoid The structured and packaged bacterial chromosome.

Segregation Movement of duplicated chromosomes or plasmids from the mother cell to each daughter cell; also called partitioning.

Introduction

As animal and protozoan cells have no wall, their cytoskeleton provides their required structure, organization and shape. Plant cells have walls, but their cytoskeleton also guides where the wall is synthesized and thus their growth and shape. These eukaryotic cells rely on three general classes of cytoskeletal proteins: tubulins, actins, and intermediate filaments. All three of these proteins form polymers. Because polymers can extend for large distances, they are capable of translating the structural organization of proteins at the molecular level (nanometers) into large scale organization at the cellular level (micrometers). For example, the regulation of tubulin polymerization into microtubules and their depolymerization back into tubulin monomers, along with the interaction among different microtubules, help to define the direction and forces during mitosis and cytokinesis, serve as tracks for intracellular transport, and provide structural strength needed for locomotion.

Because bacteria and archaea are small and have cell walls, and most have no obvious intracellular structures visible by electron microscopy, it was thought until recently that they had no equivalent of the cytoskeleton or cytoskeletal proteins. However, about 20 years ago this idea was swept aside by three concurrent revolutions. The first was the ability to sequence multiple bacterial genomes, which revealed striking similarity between certain bacterial proteins and eukaryotic actin and tubulin. The second was the large number of protein atomic structures that were solved, allowing proteins with limited sequence similarity to be compared for structural similarity. The third was the ability to visualize genetically-encoded fluorescent tags in intact bacterial cells. Fusion of a jellyfish green fluorescent protein (GFP) or its derivatives to any protein of interest results in a fluorescent pattern that reflects the localization of only that protein in a living cell. Consequently, it was discovered that proteins such as bacterial homologs of tubulin, actin and intermediate filaments localized in specific and dynamic patterns in bacterial cells, often as polymers. Genetic experiments on these proteins indicated that they play crucial roles in cell growth and shape, consistent with their hypothesized cytoskeletal functions, and biochemical studies confirmed that they could assemble into polymers in vitro. These findings and discoveries of uniquely bacterial cytoskeletal proteins have ushered in a new era of bacterial cell biology, providing unexpected insights into the evolution of the cytoskeleton.

The Bacterial Tubulin Cytoskeleton – FtsZ

Prior to 1991, little was known about subcellular organization of most bacteria, particularly those such as *Escherichia coli* that have no obvious internal structure. The breakthrough occurred when the FtsZ protein, essential for cell division in most bacteria, was successfully localized by immunogold labeling to a ring (called the Z ring) at the division site at the cell midpoint. This Z ring is comprised of polymers of FtsZ that are anchored to the inner surface of the cytoplasmic membrane at the cell center. FtsZ is a GTPase, and it assembles into protofilaments in a GTP-dependent manner. This GTP-dependent assembly, along with high structural similarity to tubulin confirmed by crystal structures and the sharing of a short sequence called the “tubulin signature”, clearly indicates that FtsZ is a tubulin homologue. This was surprising at the time, given that animal cell cytokinesis uses a ring of actin, not tubulin. FtsZ is widely conserved throughout several kingdoms of life. Its homologs are present not only in most bacteria, but also in plant chloroplasts, where they aid in chloroplast fission, and in a large branch of the archaea (euryarchaea), where their roles are still unclear but may be involved in regulating cell shape.

Although it is a tubulin homologue, FtsZ is clearly a primitive version, as it does not form hollow microtubules, nor does it consist of two distinct alpha and beta subunits. Nevertheless, there is considerable evidence that FtsZ likely acts at a level higher than single protofilaments. For example, lateral interaction among FtsZ protofilaments is stimulated *in vitro* by several proteins, including Zaps (Z associated proteins) in *E. coli*, and there is evidence for FtsZ protofilament bundling *in vivo* by these proteins as well. Other bacterial species feature Zap-like proteins, or have FtsZ proteins with high intrinsic ability to laterally interact. Such interactions are likely regulated, as too much or too little lateral interaction between FtsZ protofilaments can interfere with normal cell division.

The Z ring is highly dynamic. When *E. coli* grows in rich medium, Z rings at mid-cell form shortly after the birth of newborn cells, but do not begin to constrict until considerably later in the cell division cycle, guiding the growing division septum behind it (Fig. 1). When the ring finally constricts, studies with FtsZ–GFP fusions indicate that FtsZ subunits are released from the ring into the surrounding cytosol. This suggests that constriction of the Z ring, and subsequent cytokinesis, is driven by the loss of subunits from protofilaments that are bound to the cytoplasmic membrane. In addition to this turnover during ring contraction, the rate of turnover of FtsZ subunits between the ring and cytosol is very rapid, with a half-time of <10 s. This suggests that the pool of cytoplasmic FtsZ is large and mobile, and it has been estimated that 60%–70% of the FtsZ in the cell is not in the ring.

There have been some recent breakthroughs in the mechanistic understanding of the Z ring and how its dynamics drive formation of the division septum. Super-resolution microscopy studies using 3D structured illumination microscopy (3D-SIM) and Photoactivated Localization Microscopy (PALM) suggest that the Z ring is not a continuous polymer or polymers, but instead comprised of several aggregates of FtsZ polymers distributed in a loose network (Fig. 2, Movie 1). Recently, super-resolution fluorescence microscopy was crucial for discovering that these FtsZ aggregates migrate processively around the circumference of the Z ring by a mechanism called treadmilling. Treadmilling, often observed with eukaryotic filamentous actin and microtubules, occurs when protein subunits are added preferentially to one end of a polymer while removed from the opposite end, and is a way

Bacterial division: FtsZ treadmills to build a beautiful wall. *Current Biology* 27, 301–303. <https://dx.doi.org/10.1016/j.cub.2017.03.019>.

to achieve large-scale movement of a polymer by regulating monomer-monomer interactions at the nanometer scale. The treadmilling speed of FtsZ polymers is regulated by GTP hydrolysis and has an important role in regulating the dynamics of cell wall synthesis enzymes needed to form the division septum, which also comigrate with the FtsZ polymers around the cell circumference (Fig. 3). However, it is not yet known how the treadmilling FtsZ protofilaments coordinate with each other or interact with the many additional membrane-bound proteins attached to the Z ring. Other high resolution methods to explore the nanometer range such as whole-cell cryo-electron tomography (see below) will likely provide further structural insights into the structure of the FtsZ cytoskeleton.

Supplementary material related to this article can be found online at <https://dx.doi.org/10.1016/B978-0-12-811736-1.90741-4>.

Like microtubules, FtsZ assembly is the target of several inhibitors. Some are naturally occurring, such as viriditoxin; others are synthetic, including benzamide derivatives such as PC58538. Other FtsZ inhibitors include small proteins that are produced endogenously, such as Sula or MciZ of *E. coli* or *Bacillus subtilis*, respectively, in response to specific environmental conditions. In addition, peptides encoded by infecting bacteriophages, such as Kil from phage lambda, specifically inhibit FtsZ assembly and may confer a selective advantage during phage infection.

Alternative Tubulin-Like Cytoskeletal Elements

FtsZ is now just one prominent member of a family of bacterial tubulins (Fig. 4). Another family includes bacterial microtubules (bMTs) of the Verrucomicrobial family of bacteria, encoded by two genes, bTubA and bTubB. As the name implies, these tubulin homologs are much more like tubulin than FtsZ: they coassemble to form GTP-dependent heterodimers, and in the cell form long narrow microtubule-like structures consisting of 4–5 protofilaments instead of the 13 protofilaments that comprise eukaryotic microtubules. Interestingly, although eukaryotic tubulin requires chaperones for proper folding and function, these mini-microtubules do not. This suggests that bTubA and bTubB evolved from a more primitive microtubule system that was probably acquired by horizontal gene transfer. But like other microtubules as well as FtsZ, the mini-microtubules can treadmill, and even display rapid depolymerization (dynamic instability) typical of microtubules. The function of these mini-microtubules in the physiology of these organisms is not yet known, although their proximity to cellular projections in their prosthecate bacterial hosts suggests that they may be involved in growth and/or rigidity of these projections. Furthermore, the ability of the mini-microtubules to mimic eukaryotic microtubules without the need for chaperones will likely be very useful for synthetic biology applications, including constructing artificial microtubules.

Another bacterial tubulin family is encoded by large plasmids of the *Bacillus* group, including *Bacillus anthracis*, *Bacillus cereus*, and *Bacillus thuringiensis*. The *B. thuringiensis* member of this family, called TubZ, is encoded by the pBtoxis plasmid that also encodes the well-known insect toxin. TubZ, which is a divergent form of FtsZ that also has significant similarity to tubulin, forms highly dynamic polymers that curve along the cytoplasmic membrane of both the native host and *E. coli* by treadmilling. Such behavior may reflect a role in plasmid partitioning. A protein similar to TubZ, called RepX, is encoded by pXO1, the toxin-encoding

Fig. 4 Phylogeny of tubulins. Reprinted from Wagstaff, J., Löwe, J., 2018. Prokaryotic cytoskeletons: Protein filaments organizing small cells. *Nature Reviews Microbiology* 16, 187–201. <https://dx.doi.org/10.1038/nrmicro.2017.153>.

plasmid of *B. anthracis*. This protein is essential for plasmid maintenance, although its localization and dynamics have not yet been characterized. TubZ is double helical, which suggests that in contrast to FtsZ, TubZ has a mitotic function more similar to that of eukaryotic microtubules.

Another example of a mitotic-like function of a bacterial tubulin comes from a set of large bacteriophages that infect certain *Pseudomonas* species. These phages encode their own homologue of tubulin, called PhuZ, which assembles into a three-stranded polymer that forms a mitotic spindle-like structure extending the length of the cell during phage infection. The PhuZ filaments in this spindle display dynamic instability, which, as with microtubules, results in rapid depolymerization of the entire structure. This dynamic cell-spanning spindle nucleates at both cell poles, with each half growing unidirectionally and tethered to a developing nucleus-like compartment that harbors the phage replication factory at midcell. The pushing forces from this PhuZ spindle end up organizing and centering the replication compartment.

Finally, just as bacterial tubulins are not limited to FtsZ, FtsZ homologs are not limited to bacteria. A large branch of the archaea called euryarchaea carry two paralogs of FtsZ, both of which are likely involved in cytokinesis of these bacteria-like cells. Multiple paralogs of FtsZ are also widespread in plant chloroplasts, where they assemble as rings to divide and distribute these organelles. FtsZ paralogs are also present in the mitochondria of protists such as *Dictyostelium*. However, FtsZ is not present in archaea outside of the euryarchaea, nor is it present in mitochondria of higher eukaryotes.

The Bacterial Actin Cytoskeleton

Bacteria also have multiple homologs of actin that are involved in everything from cell division (FtsA), plasmid partitioning (ParM and AlfA), organelle organization (MamK), and regulation of cell growth and chromosome segregation (MreB) (Fig. 5). The most widely conserved of these are FtsA and MreB, and in species such as *E. coli*, these proteins are essential for viability.

FtsA is a divergent homologue of actin that is required for proper cell division in a wide variety of species, although it is absent in archaea and in some families of bacteria such as the Actinobacteria. It localizes to the Z ring, binds directly to FtsZ, and its localization is dependent on functional FtsZ. Unlike actin, FtsA has a C-terminal membrane targeting sequence, which is required for tethering dynamic FtsZ protofilaments to the inner surface of the cytoplasmic membrane. Purified FtsA from *Streptococcus pneumoniae* forms helical pairs of protofilaments, and purified *E. coli* FtsA binds tightly to lipid membranes and forms curved polymers on them, often as closed minoring forms (Fig. 6). Although FtsA binds ATP like actin, FtsA subunits structurally interact in a different orientation compared with subunits of F-actin, and the atomic structures of FtsA from *Thermotoga maritima* and *Staphylococcus aureus* already suggest that different FtsA proteins polymerize in distinct orientations from each other. The membrane targeting sequence also strongly influences FtsA's oligomerization properties, because when it is removed, FtsA forms straight bundled polymers that fail to bind to the membrane.

Recent high resolution studies with FtsZ and FtsA have shed light on how this primitive tubulin-actin interaction functions in the cell. When purified FtsZ is added to FtsA on lipid membranes in the presence of ATP, FtsZ polymers align and move by treadmilling, mimicking their behavior in the cell. Although it is not yet known if FtsA minirings exist in cells, when assembled on lipid monolayers they promote alignment of FtsZ protofilaments but inhibit them from directly interacting. Cryo-electron tomography of intact bacterial cells has shown that FtsA polymerizes closest to the membrane, with FtsZ polymers assembling parallel to the FtsA polymers. It should be emphasized that in addition to binding FtsZ and tethering it to the membrane, FtsA is truly multifunctional as it also acts to recruit other proteins to the cell division machinery.

MreB was originally identified by a mutation that caused normally rod-shaped *E. coli* cells to round up. The MreB protein is highly similar to actin, and like F-actin, MreB assembles into double stranded protofilaments in the presence of ATP. However, an important distinction is that MreB filaments are antiparallel, which should prevent them from net directional movement by treadmilling. In rod-shaped cells such as *E. coli* or *B. subtilis*, MreB was originally found to form a helix along the length of the cell. In *B. subtilis*, two other MreB-like paralogues also exist (Mbl and MreBH) that also appear to form helical filaments with somewhat different localization patterns. Recent high resolution microscopic imaging of MreB suggests that MreB forms mobile patches and

short filaments on the membrane instead of or in addition to continuous helices (Movie 2), and these patches move around the membrane circumferentially in response to cell wall biosynthetic activity. Although these short filaments depend on cell wall synthesis for their mobility, they function to target wall synthesis to regions of negative membrane curvature. It is thought that this self-reinforcing feedback mechanism results in maintenance of rod shape. Moreover, local insertion of peptidoglycan mediated by these MreB patches results in left-handed twisting of the entire cell during growth. During the cell cycle of *Caulobacter crescentus* or *E. coli*, a portion of MreB moves from the sidewall to the Z ring. The function of this relocation may be to redirect cell wall biosynthesis to the area of septum growth. If MreB localization to the Z ring is driven by a direct interaction with FtsZ, which has been suggested for *E. coli*, it would be another example of interaction between a tubulin and actin in bacteria in addition to the FtsA–FtsZ interaction.

Supplementary material related to this article can be found online at <https://doi.org/10.1016/B978-0-12-811736-1.90741-4>.

The absence of MreB in cocci, as well as the loss of rod shape when MreB is inactivated, is entirely consistent with these functions of MreB in rod-shaped bacteria. Like FtsA, MreB interacts with the cytoplasmic membrane using an amphipathic helix, in this case at its N terminus. MreB also interacts with MreC and MreD, which are transmembrane proteins that are encoded within the same operon as *mreB*. Other proteins interact with MreB and colocalize with MreB. In *E. coli*, these include MurG, a key cell wall biosynthetic enzyme, and FtsZ itself (see below). In a striking evolutionary twist, the Chlamydia family of bacteria, which are obligately intracellular, lack FtsZ and instead use MreB to divide by binary fission.

Intriguingly, a number of rod-shaped bacteria such as the rhizobia, corynebacteria, and mycobacteria lack MreB homologs, prompting the question of how they achieve cylindrical growth without MreB as a guide. Labeling of nascent cell wall synthesis of *Corynebacterium glutamicum* by fluorescent vancomycin indicates that its new wall growth occurs solely at the cell poles, suggesting that this may be a mechanism for the other MreB-less rod-shaped species as well. Streptomycetes, which contain MreB homologs, also grow primarily at cell poles or by initiating branches, which are essentially new poles. Streptomycetes do not require MreB for vegetative growth but instead to coordinate growth during sporulation. In the case of streptomycetes and corynebacteria, a protein called DivIVA is crucial for proper polar growth. In both species, disruption of DivIVA causes severe shape abnormalities, and DivIVA localizes mostly at the cell poles, indicating that it orchestrates wall growth at the cell tips. Interestingly, DivIVA is cytoskeletal-like, as it has weak homology to myosins and forms oligomeric structures. Moreover, DivIVA can localize to cell poles in non-native species, including *E. coli* and even fission yeast, suggesting that it recognizes negative membrane curvature or a specific phospholipid domain that is enriched at that curvature. The common thread among rod-shaped bacteria that lack MreB seems to be polar growth, which would obviate the need for a cytoskeletal coordination of sidewall growth. Indeed, like their Gram positive corynebacterial counterparts, Gram negative rhizobia were shown to grow by unipolar extension by using recently developed fluorescent amino acid analogs such as HADA.

By analogy to actin, MreB is subject to inhibition by specific small molecules. One of these, called A22, rapidly abolishes the regular localization of MreB in cells, suggesting that it disassembles MreB polymers. Continued exposure to A22 eventually causes cells that depend on MreB for rod shape to round up. Interestingly, when A22 is added to *C. crescentus* cells, chromosome segregation is inhibited relatively rapidly, before any cell shape changes become visible. The inhibitory effect is mainly exerted on the chromosomal origins of replication, which fail to migrate properly when MreB is inactivated by A22. This suggests that MreB is involved in chromosome segregation, although any role of MreB in this process remains unclear as it has been difficult to rule out indirect effects of cell growth perturbation on replication origin segregation.

Bacterial Actin-Like Proteins are Ubiquitous

In addition to crenactin, which is a homologue of actin present in some crenarchaea (Thermoproteales) that is implicated in cytokinesis, diverse actin families in bacteria are still being discovered and characterized. The prototype for these is ParM, which is encoded by an *E. coli* plasmid, R1. ParM assembles into a left-handed double helical filament that extends bidirectionally between two replicated plasmids, helping them move apart into daughter cells. The mitotic spindle-like ParM filaments connect to the plasmid DNA via a kinetochore-like protein adaptor, ParR, which binds to a specific DNA sequence element (*parC*) on the plasmid. By themselves, ParM polymers are ATP-dependent and dynamically unstable, so like microtubules, they are prone to rapid depolymerization once their growing ends become destabilized. This rapid depolymerization occurs after ATP hydrolysis, and can be inhibited by the presence of a bound ParR-*parC* “cap” at the filament ends. The ParM/ParR/*parC* system has recently been reconstituted *in vitro*. The purified ParR/*parC* complex binds to the ends of ParM polymers, riding along the growing filament ends and inhibiting the dynamic instability of the polymers. It is likely that ParM filaments provide the mechanical force to push *parC*-containing plasmids apart.

Other ParM-like actin homologs are present in diverse species, and their overall mechanisms of action are similar. For example, Alfa promotes segregation of a low copy *B. subtilis* plasmid by forming a highly dynamic polymer bundle. Like ParM, Alfa uses an adaptor protein (AlfB) to bind to plasmid DNA in order to move plasmids apart in the cell. But unlike ParM, Alfa polymers can elongate in one direction and are thus able to move by treadmilling. The regulation of the Alfa spindle-like apparatus occurs through the activity of AlfB. When bound to its DNA target, AlfB permits Alfa to polymerize into a spindle. However, when unbound to DNA, AlfB instead destabilizes the Alfa polymer bundle, allowing Alfa to reassemble into a new spindle that will push the plasmids farther apart. AlpC is another well-studied actin homologue that forms a mitotic spindle-like structure, this time encoded by a prophage present in *C. glutamicum*. Like ParM, AlpC binds to specific sites on phage DNA (*alpS*) through an adaptor protein, AlpA, and undergoes dynamic instability. When AlpA is not bound to DNA, it promotes AlpC disassembly; however, when

bound to its DNA target, AlpC is free to polymerize into the spindle structure that spatially organizes phage DNA and promotes its replication.

In addition to mitotic spindle structures, actin-like proteins have been found to be important for forming and positioning organelles in certain bacteria. The best known of these is MamK, an actin homologue from the magnetotactic bacterium *Magnetospirillum magneticum*. These bacteria rely on the earth's magnetic field to guide their motility, and contain iron-containing organelles called magnetosomes that need to be anchored in place in order to align the cells properly with the magnetic field. MamK accomplishes this by assembling into dynamic, ATP-dependent filaments that stabilize the chain-like magnetosomes, preventing their diffusion, and ensuring their proper partitioning into daughter cells. MamK filaments form independently of MreB, and like those of many bacterial actins, these filaments extend for significant lengths within the cell and consist of double stranded parallel protofilaments (Fig. 5). Partitioning of the organelle occurs after the magnetosome chain is severed by cytokinesis and remains at the new poles of the daughter cells, at which point MamK helps to reposition the magnetosomes.

Bacterial Intermediate Filaments

The third major eukaryotic cytoskeletal element, intermediate filaments (IFs), is also represented in at least one bacterial species. *C. crescentus* is so named because of its vibrioid crescent shape. A protein called crescentin is required for this shape, because a null mutant in the gene it encodes results in straight, rod-shaped *C. crescentus* that otherwise retains its cell polarity. Crescentin localizes as a long polymeric structure to the concave side of the cell, suggesting that it is directly or indirectly associated with the inhibition of growth that causes the opposite side of the cell to curve outward. However, a function in membrane rigidity, analogous to the function of many intermediate filaments in eukaryotes, cannot be ruled out. Remarkably, when crescentin is produced in *E. coli*, it induces cells to become curved, although producing it in the more closely related *Agrobacterium tumefaciens* had no effect on its rod shape. This effect indicates that crescentin is sufficient to induce curvature, perhaps because both *E. coli* and *C. crescentus* contain MreB and grow by sidewall synthesis, in contrast to *A. tumefaciens*, which lacks MreB and grows by polar extension. Purified crescentin self-assembles into long filaments that are 10–20 nm wide and independently of nucleotides, characteristic of IFs such as vimentin. Crescentin filaments in cells are not dynamic, which makes their nucleation and distribution during cell division open questions. Another open question is how many bacterial IFs exist; IFs share low sequence similarity, so it is difficult to know how widely conserved such IF homologs might be in bacteria without directly testing candidate genes and proteins for activity.

Other bacterial proteins have IF-like properties. Like crescentin, some of them are involved in controlling cell growth and shape. For example, two IF-like proteins, Scy and FilP, localize near growth zones at the hyphal tips of *Streptomyces*, forming a protein machine along with DivIVA. As mentioned earlier, DivIVA is the scaffold for tip growth. Scy colocalizes with DivIVA, indicating that both proteins are present where nascent peptidoglycan is being synthesized. FilP, on the other hand, lags behind and localizes in its own sub-polar zone, distal from the pole and from DivIVA and Scy. It is thought that Scy is directly involved in wall synthesis at the tip, while FilP acts to provide a rigid scaffold for the growing tip. How FilP and Scy partition their activity and their localization, especially given their structural similarity, is not known.

Polymerizing Walker a Cytoskeletal ATPases

There are many other bacterial proteins that form filaments, including AglZ of myxobacteria and CTP synthase of *E. coli*, that are not homologs of eukaryotic cytoskeletal proteins. However, one family of ATPases that forms polymers and generally displays cytoskeletal behavior deserves mention: the Walker A cytoskeletal ATPases (WACA). These proteins share a deviant Walker A motif, KGGXXGKT, with two conserved lysines that are crucial for ATP binding and hydrolysis. These proteins generally assemble into polymers using ATP, and their ability to dynamically relocate in the cell in response to other factors has important roles in cellular organization. One founding member of this family is MinD, which in *E. coli* teams up with a small protein called MinE to oscillate from cell pole to cell pole. Like FtsA and MreB, MinD uses an amphipathic helix to bind to the inner surface of the cytoplasmic membrane, where it recruits an inhibitor of FtsZ assembly called MinC. Without MinE, MinD binds the membrane statically. But the binding of MinE to MinD stimulates the latter's ATPase activity, dislodging it from the membrane where it can diffuse, rebind ATP, and rebind the membrane at the opposite cell pole (Movie 3). The bipolar gradient of MinC and MinD resulting from the pole to pole oscillation promotes maximum FtsZ assembly at the midpoint between the cell poles, thus helping to define the cell division site. Another WACA is ParA, which powers the assembly of its DNA binding partner, ParB, on chromosomal DNA and helps to partition chromosomes in some bacterial species. Other ParA-like proteins include Soj and SopA, which oscillate over the nucleoid. Like MinD, their dynamic relocation requires interaction with another protein factor. Both ParA and MinD form polymers in vitro, although the physiological relevance of this polymerization is still controversial. However, it is notable that MinC and MinD form alternating copolymers that are similar to those formed by septins, which are cytoskeletal GTPases that form ring structures in eukaryotic cells used for protein assemblies and cellular compartmentalization.

Supplementary material related to this article can be found online at <https://dx.doi.org/10.1016/B978-0-12-811736-1.90741-4>.

Other WACAs important for cellular organization in bacteria include MipZ of *C. crescentus* and PomZ of *Myxococcus xanthus*. Like MinD, both proteins play an important role in positioning the Z ring, and loss of function of either causes cell division defects. MipZ forms a bipolar gradient similar to that of MinD, except there is no pole to pole oscillation. Instead, like ParA, MipZ binds to ParB, which in turn binds to a region of chromosomal DNA near the origin of replication (oriC) that serves as a centromere-like sequence. MipZ is also an inhibitor of FtsZ assembly, like MinC. The result of these activities is that FtsZ is prevented from assembling near the

middle of *C. crescentus* cells until oriC is duplicated and partitioned to daughter cells. PomZ was discovered more recently and functions as a positive spatial regulator of Z ring assembly instead of a negative regulator. Along with its partner proteins PomX and PomY, PomZ localizes to the nucleoid near midcell prior to FtsZ and promotes Z ring assembly.

The Cytoskeleton of Wall-Less Mycoplasmas

This article has dealt mainly with cells that have walls, and use cytoskeletons to guide their growth and organization. Mycoplasmas, on the other hand, are very small gliding bacteria that lack cell walls. Their cytoskeleton assumes an even greater importance, as it is necessary for the distinctive behavior and morphologies of these organisms. Probably the most well-characterized part of their cytoskeleton is the terminal organelle. In *Mycobacterium pneumoniae*, this organelle is required for pulling the daughter cells apart during cytokinesis as well as for adherence to host cells. The organelle is an extension of the cell that by electron microscopy consists of paired parallel bars ending with a button-like structure. Several proteins are part of the organelle, including HMW2 and P28, which are part of the electron-dense core, and HMW3, a major component of the terminal button. Other proteins localizing to the terminal organelle include P1, P30, P41, and P65. Duplication of new terminal organelles takes place adjacent to an existing one, followed by migration of one organelle to the opposite side of the cell. Gliding temporarily stops during this process, then continues to help pull the cell poles apart during cytokinesis. Many mycoplasma species have an FtsZ homologue that is probably required for cytokinesis, but lack other homologs of cell division proteins. This suggests that FtsZ alone may provide the force to pinch mycoplasma membranes during cytokinesis. However, one species of mycoplasma, *Ureaplasma urealyticum*, lacks an FtsZ homologue, suggesting that it may use its own specialized cytoskeleton for cell division.

Conclusions and Outlook

From what was nothing 25 years ago, there is now an astonishing array of bacterial cytoskeletal proteins that have been characterized in detail, and many more still to understand. In addition to the major classes of proteins discussed here, there are others recently discovered but not as well characterized, such as bactofilins and bacterial homologs of dynamins and spectrins, which have important roles in cell growth, shape, and membrane dynamics. Other candidates for cytoskeletal functions include metabolic enzymes such as CTP synthases that form polymers. With the advent of cryo-electron tomography and other more powerful *in situ* techniques such as single molecule imaging and TIRF microscopy, along with the advances in proteomics, the goal of understanding how these cytoskeletal proteins cooperate to operate an entire cell seems more likely than ever, and it is likely that a bacterial cell will be the first.

Glossary

AglQ A component of the *Myxococcus xanthus* gliding motility motor that is related to flagellar motor protein MotB.

AglR The component of the *Myxococcus xanthus* gliding motility motor that is related to flagellar motor protein MotA.

AglS A component of the *Myxococcus xanthus* gliding motility motor that is related to flagellar motor protein MotB.

MreB Bacterial cytoskeletal protein that is involved in *Myxococcus xanthus* gliding.

Cryo-EM-tomography Electron microscopy technique used to view intact cells or cell fractions in a frozen, hydrated state at high resolution that can be used to generate 3-dimensional images.

Gas vacuole Clusters of gas vesicles.

Gas vesicle Protein shells filled with gas that provide buoyancy.

Gliding motility Active movement of bacteria over surfaces that does not involve flagella or pili.

Periplasm Region between the cytoplasmic membrane (inner membrane) and outer membrane of a Gram negative bacterial cell.

Pilin The protein that is the main component of the filament of a bacterial pilus.

PilB ATPase involved in type IV pilus assembly.

PilC Cytoplasmic membrane protein that is part of the type IV pilus motor.

PilQ Protein that makes the outer membrane pore for type IV pili.

PilT ATPase involved in type IV pilus retraction and disassembly.

Sliding motility Passive movement of bacteria over surfaces as a result of forces generated in a colony during cell growth.

SprB *Flavobacterium johnsoniae* gliding motility adhesin that is propelled rapidly along the cell surface.

Twitching motility Movement of bacteria over surfaces using type IV pilus extension and retraction.

PMF Proton motive force

T9SS Type IX protein secretion system

Background and Experimental Approaches

The involvement of flagella in bacterial motility was suggested in the 1800s, and the functioning of these structures as rotary propellers was recognized in 1973 by Berg and Anderson. In contrast, all other forms of bacterial motility (nonflagellar motility) remained mysterious until more recently, and some are still poorly understood. In recent decades, a combination of experimental approaches including genetic analyses, electron microscopy (EM), fluorescence microscopy, biochemical approaches, and comparative genome studies have elucidated the basic mechanisms for several forms of bacterial nonflagellar movement. Genetic analyses involved the isolation of mutants that had lost the ability to move. This allowed identification of the genes and proteins required for movement. Many of the proteins that were required for motility were components of the novel motility machineries discussed below. The development of high resolution EM approaches, and most recently of cryo-EM-tomography, allowed the visualization of the previously invisible motility machines in intact cells or cell fractions. This approach was used to compare wild-type and nonmotile mutant cells to identify motility structures. Use of fluorescent molecules to label components of the motility machinery that had been identified by genetic or biochemical analyses allowed visualization of components of the motility machines in motion and the development of models for bacterial nonflagellar motility. Use of these approaches resulted in the recognition of the four different mechanisms for active bacterial movement over surfaces that are described below: type IV pilus-mediated motility, myxobacterial gliding motility, *Flavobacterium* gliding motility, and *Mycoplasma* gliding. Two forms of active nonflagellar swimming motility are also known. The movement of these bacteria has received less attention and many mysteries remain regarding their movements.

Type IV Pili and Twitching Motility

Type IV pili are long thin dynamic structures (about 6 nm in diameter and up to 10 μm long) that extend from the cell, usually from a cell pole. Type IV pili and twitching motility are most common in Gram negative bacteria. These include, for example, *Pseudomonas aeruginosa*, *Neisseria gonorrhoeae*, and *Myxococcus xanthus*. Type IV pili are also found in a few Gram-positive bacteria, such as *Clostridium perfringens*.

Type IV pili are comprised primarily of many copies of pilin proteins (PilA) with smaller numbers of adhesins present at the tip. An individual pilus spans the entire cell envelope, from the cytoplasmic membrane through the outer membrane (Fig. 1). The involvement of pili in twitching motility was first suggested in the 1980s by the realization that mutants that lacked pili were nonmotile and that antisera that bound to pili blocked motility. At that time, Bradley proposed that pilus retraction was responsible for cell movement, an idea that was later confirmed by genetic, molecular, biochemical, and microscopic studies.

Genetic and biochemical analyses identified dozens of proteins (at least 35 for *P. aeruginosa*) involved in twitching motility. These include at least 20 that are involved in pilus biogenesis. Among these, PilA is the primary structural subunit of the pilus, PilB is the ATPase that powers pilus assembly (extension), PilT is the ATPase that powers pilus disassembly (retraction) and PilQ is the outer membrane secretin that makes a pore through which the pilus protrudes. A key feature of the pilin protein PilA is its ability to exist in two forms, both of which rely on a hydrophobic α -helix. This hydrophobic region anchors the protein to the cytoplasmic membrane, with its hydrophilic portion apparently extending into the periplasm. During pilus assembly, pilin monomers are recruited from the membrane. During this process, the hydrophobic helices of the PilA proteins interact with each other and become buried at the center of the growing pilus cylinder. Biochemical and genetic analyses revealed that pilus assembly is catalyzed by the rotating pilus motor comprised of PilB and PilC. This ATP driven motor is thought to scoop PilA monomers from the membrane and add them to the base of the growing pilus. This process is repeated many times as the pilus grows. Importantly, this process is reversible. When PilT replaces PilB, ATP hydrolysis results in removal of PilA from the base of the pilus, returning the pilin protein into the cytoplasmic membrane, and resulting in retraction of the pilus.

How do type IV pili result in cell movement? At the tip of the pilus is an adhesin. When this adhesin attaches to a surface this is sensed by a poorly understood mechanism, and PilT initiates removal of PilA monomers from the base, melting them back into the cytoplasmic membrane. As the pilus shortens it remains attached at its tip to the external surface, and the cell is dragged toward this point (Fig. 2). Multiple pili can extend from the pole, and function together to pull the cell. PilA monomers in the membrane are apparently recycled to construct new pili, allowing the cell to continuously crawl in the same direction. Reversal of cell movement involves assembly and disassembly of pili at the opposite cell pole. For at least some bacteria secreted polysaccharides also play a role in twitching. These may coat the substratum and provide points of attachment for pili, or may alter the friction between the cells and the substratum allowing the cells to be pulled more effectively by pilus retraction.

Fig. 1 The type IV pilus. The type IV pilus machinery spans the bacterial cell envelope. The pilus itself, which extends from this machine, is comprised primarily of many copies of the pilin protein PilA (blue) with smaller amounts of minor pilins. The pilus extends through an outer membrane channel comprised of PilQ proteins. Adhesins (yellow) are found at the distal tip of the pilus. An ATP-powered motor at the base of the machine pulls PilA monomers from the cytoplasmic membrane and inserts them into the base of the growing pilus. Disassembly of the pilus, also powered by ATP hydrolysis, results in retraction of the pilus, and returns the PilA proteins to the cytoplasmic membrane. Assembly and disassembly involves two ATPases (PilB and PilT respectively) that function with PilC. Other proteins involved in pilus biogenesis and function have been omitted from this model for simplicity.

Fig. 2 Movement of a bacterial cell by type IV pilus-mediated twitching motility. Pili extend from the front pole of the cell and contact a surface. Retraction of the pili results in cell movement. Extension and retraction of pili from the opposite pole results in movement in the opposite direction. From McBride, M. J. (2001). Bacterial gliding motility: Multiple mechanisms for cell movement over surfaces. *Annual Reviews of Microbiology* **55**, 49–75.

Studies of *N. gonorrhoeae* and *P. aeruginosa* provided direct evidence for cell movement by pilus retraction. The most dramatic evidence was provided by Skerker and Berg in 2001 and involved examination of cells whose pili had been fluorescently labeled. Pili were observed to extend and retract from a stationary cell. Cells actively moved when pili that were attached to a surface retracted. Biophysical analysis of retraction of pili attached to latex spheres revealed that the pilus motor is one of the strongest biological motors known. In addition to the roles of type IV pili in cell movement, they are also involved in many other processes, including attachment of cells to surfaces, uptake of DNA by transformation and conjugation, and infection by viruses that use pili as receptors to attach to the cell. The dynamic nature of type IV pili appears to be important in each of these processes.

Recent cryo EM-tomography experiments provided stunning insights into the structure of type IV pili. Analyses of wild type and mutant cells allowed elucidation of the overall structure of the pilus and the localization of many of its components in intact cells. This includes not only the proteins mentioned above, but many others that form a series of rings in the cell envelope that support the growing pilus (Fig. 3).

A number of genes regulate the expression of pilus genes in response to environmental stimuli, so that pili are only produced and function when needed. Some of these control the location of the pili at the appropriate pole, or control extension and retraction of individual pili. For example, *P. aeruginosa* cells migrate in chemical gradients using a set of signal transduction proteins related to the well-studied chemotaxis proteins of swimming bacteria that control the direction of rotation of flagella. Exactly how these function to control pilus function is not yet known.

Myxobacterial Gliding Motility

Myxobacteria are rod-shaped, social gliding bacteria that crawl over surfaces in groups in search of food. Myxobacteria digest polymers such as polysaccharides and proteins. Many of them are predators that attack and digest bacteria and other organisms. The cells swarm over surfaces cooperatively digesting their prey. When they run out of food, thousands to millions of myxobacterial cells aggregate to form a fruiting body. Within the fruiting body the cells differentiate to become dormant myxospores. When the myxospores experience favorable conditions again, they germinate and generate a new feeding swarm. Myxobacteria are Gram-negative bacteria that belong to the δ proteobacterial phylum.

Myxobacterial motility has been most well studied for cells of *M. xanthus*, which use two independent machines to move over surfaces. As described in the previous section, they use type IV pilus extension and retraction to move by twitching motility. This allows *M. xanthus* cells to move in groups and is often referred to as “social motility” (S-motility). The second form of movement allows more efficient movement of individual cells and is called “adventurous gliding motility” (A-motility), or sometimes just “gliding motility.”

The possibility of multiple *M. xanthus* motility machines was suggested in the 1970s by genetic analyses. Hodgkin and Kaiser isolated numerous mutants that were partially defective in cell movement, and grouped these into the “social” and “adventurous” categories mentioned above. Most completely nonmotile mutants had two mutations; one that disrupted the social motility machine, and another that disrupted the adventurous motility machine. These initial studies also implicated pili in social motility,

Fig. 3 Type IV pilus structure. Type IV pili were observed in intact *M. xanthus* cells by cryo-EM tomography. (A) An *M. xanthus* cell on an EM grid. Bar indicates 500 nm. (B) Higher magnification of the boxed region from (A). White arrows indicate type IV pilus machines with pili extending from the cell. Black arrow indicates an empty type IV pilus machine. Outer and inner membrane (OM and IM) are indicated and bar indicates 50 nm. (C) Pilus structure at higher resolution obtained by averaging images of multiple pilus machines. (D) Cartoon illustrating the structure of type IV pilus machines with and without pilus filaments. Type IV pili extend and retract to pull cells forward. ATP hydrolysis in the cytoplasm is thought to cause the PilC protein in the inner membrane (orange) to rotate and transfer pilin proteins from the inner membrane into the growing pilus. This process is reversed during pilus retraction. Modified from Chang, Y. W., Rettberg, L. A., Treuner-Lange, A., Iwasa, J., Sogaard-Andersen, L., and Jensen, G. J. (2016). Architecture of the type IVa pilus machine. *Science* **351**, aad2001.

since these were absent from cells of many social motility mutants. Molecular analyses identified the nature of the mutated genes and the proteins that they encode. Many of the social motility proteins were involved in type IV pilus assembly or function and were similar to those of other bacteria that use twitching motility. The adventurous motility proteins on the other hand were mostly novel. Analysis of A-motility mutants revealed that these proteins comprise a unique motility machine within the cell envelope.

The motor driving A-motility was recently identified. It is comprised of three cytoplasmic membrane proteins, AglQ, AglR, and AglS, that harvest the proton gradient across the membrane to power cell movement. This proton gradient is also referred to as the

proton motive force (PMF). AglQ, AglR, and AglS are related to components of other PMF-driven motors including the rotary flagellar motor (MotA and MotB) and the motor that energizes various outer membrane transport processes (TolQ and TolR). AglR is similar to MotA/TolQ and AglQ and AglS are both similar to MotB/TolR. Unlike the flagellar motor and the Tol complex, the Agl motor complex is apparently not anchored to the peptidoglycan cell wall, and instead it moves along the cytoplasmic membrane following a helical path. This was demonstrated by microscopic analysis of AglR and AglQ proteins fused to fluorescent proteins. The *M. xanthus* gliding motility apparatus also includes proteins in the cytoplasm, periplasm, and outer membrane. The Agl motors in the cytoplasmic membrane appear to transiently interact with cytoplasmic, periplasmic, and outer membrane components of the machinery to result in cell movement. The cytoskeletal protein MreB appears to be involved in motility and the motors may migrate along the helical cytoskeleton. Two models are currently being considered to explain cell movement (Fig. 4). The focal adhesion model for *M. xanthus* gliding suggests that this involves propulsion of cell surface adhesins that contact the substratum over which the cells crawl. In contrast, the helical rotor model suggests that the proteins that are propelled are not expressed on the cell surface but instead are confined to the periplasm of the cell. These proteins form a moving bulge in the outer membrane that transmits the force to the substratum resulting in cell movement. A novel feature of both models is the movement of the motors in the cytoplasmic membrane along the length of the cell following helical tracks. Secreted polysaccharides are also involved in movement. These are thought to facilitate the productive interaction of cell surface components of the motility machinery with the substratum.

As with twitching motility, described above, myxobacterial gliding is controlled by signal transduction proteins related to the chemotaxis proteins that control the direction of rotation of bacterial flagellar motors. Exactly what the myxobacterial cells sense is not known, but the sensory transduction system controls cell reversals, and thus facilitates migration toward preferred environments.

Flavobacterium (Bacteroidetes) Gliding Motility

Many members of the large and diverse phylum *Bacteroidetes* exhibit a unique form of gliding motility that appears to be restricted to this phylum of Gram negative bacteria. Flagellar motility is rare or nonexistent in the phylum, as are type IV pili, but members of many genera and species exhibit gliding motility. This type of gliding has been most well studied for the soil and freshwater bacterium *Flavobacterium johnsoniae* (Fig. 5). The long slender *F. johnsoniae* cells crawl over surfaces at speeds of about 2 μm per second. They occasionally reverse direction, with the “head” becoming the “tail.” Cells may also undergo pivoting, flipping, and rotating movements when they are attached to the surface at a single point. The PMF across the cytoplasmic membrane powers these movements. As with most other gliding bacteria, the movement of individual cells results in the formation of thin spreading colonies (Fig. 5).

Genetic tools developed for *F. johnsoniae* in the 1990s were used to identify genes and proteins involved in gliding. This involved isolation of nonmotile mutants (Fig. 5) and identification of the mutated genes and the motility proteins that they encode. At least 19 proteins are involved in *Flavobacterium* gliding, and most of these are conserved in other gliding members of the phylum. One of these proteins, SprB, is a huge (669 kDa) cell surface adhesin. Microscopic analyses of cells labeled with fluorescent antibodies

Fig. 4 *M. xanthus* gliding motility. Gliding is powered by motor proteins (AglQ, AglR, AglS) that harvest the PMF and move along helical tracks associated with the inner face of the inner membrane. The two models propose different mechanisms for force transmission to the substratum. In the helical rotor model (left) the motors (purple) carry periplasmic cargo (blue) as they migrate. The moving cargo deforms the cell surface which pushes against the substratum. The focal adhesion model (right) is similar except that the cargo carried by the motors extends to the outside of the cell, and the action of the motors on these surface-exposed proteins that have attached to the substratum results in cell movement. From Nan, B. and Zusman, D. R. (2016). Novel mechanisms power bacterial gliding motility. *Molecular Microbiology* **101**, 186–193.

Fig. 5 Gliding of *F. johnsoniae* cells. (A) Characteristic movements of cells. (B) Spreading colony formed by millions of wild type cells, and nonspreading colonies formed by cells of a nonmotile *gldA* mutant. Bar in panel B corresponds to 1 mm and applies to both images. against SprB revealed that it is propelled rapidly (approximately 2 μm per second) along the cell surface. SprB proteins appear to follow a helical path as they move from one pole of the cell to the other (approximately 5–10 μm), flip around the pole, and continue back toward their original location. SprB is not the only moving cell-surface adhesin involved in motility. RemA moves in a similar way and genome analyses suggest the presence of additional semiredundant motility adhesins that may allow the cells to crawl over many different surfaces. The exact nature of the machinery that propels motility adhesins such as SprB is not known, but it is probably comprised of the other motility proteins, most of which are referred to as Gld proteins. Some of these proteins also form the core of the type IX protein secretion system (T9SS), that delivers SprB and the other motility adhesins to the cell surface. This is reminiscent of the bacterial flagellum which has a type III secretion system at its core that is involved in its assembly. The *F. johnsoniae* T9SS has many roles besides motility and secretes dozens of soluble enzymes and cell-surface localized proteins. T9SSs are confined to but common in members of the phylum *Bacteroidetes*. They are even found in some members that are nonmotile, such as the human oral pathogen *Porphyromonas gingivalis*, which uses its T9SS to secrete virulence factors.

Many proteins required for *Flavobacterium* motility have been discovered, but fundamental mysteries remain to be explored. The PMF is needed for gliding, but the components of the motors that harvest this proton gradient to propel SprB along the cell surface remain uncertain. These motors appear to rotate, and they are probably anchored to the cell wall, unlike the *M. xanthus* gliding motors described above that move freely along the cytoplasmic membrane. The *Flavobacterium* gliding motors must span the cytoplasmic membrane to harvest the PMF. Two cytoplasmic membrane proteins, GldL and GldM, that are components of the T9SS and are required for gliding may comprise these motors, but this has not been directly demonstrated. The remaining motility proteins probably comprise the rest of the machinery that connects the motors with SprB and the other cell-surface adhesins. Some of these proteins are helically arranged in the cell envelope, and may constitute the tracks that SprB follows along the cell surface. In the model for *F. johnsoniae* gliding shown in Fig. 6, multiple PMF-powered rotary motors are attached to the cell wall and propel adhesins such as SprB and RemA along looped helical tracks on the cell surface. The action of the motors on adhesins that are attached to the substratum results in forward movement and rotation of the cell. A variation that requires fewer rotary motors per cell (not shown) postulates attachment of the adhesins directly to a helical track, and movement of the entire track or sections of track, in a conveyor-belt fashion. Still mysterious is the mechanism used to control the motors to allow migration in favorable directions. Unlike the myxobacteria described above, *F. johnsoniae* and other *Bacteroidetes* lack genes related to bacterial chemotaxis genes. They probably control their motility in response to environmental stimuli but the mechanism is completely unknown.

Movement of Bacteria That Lack Cell Walls: The Mycoplasmas and Spiroplasmas

The bacterial cell wall prevents osmotic lysis, and is thus critical for survival of most bacteria. Members of the genus *Mycoplasma* and related bacteria in the class Mollicutes lack peptidoglycan, a critical component of the bacterial cell wall of nearly all bacteria. Electron microscopic examination confirmed that mycoplasmas, most of which are parasitic, lack cell walls. Given the demonstrated importance of the cell wall to the survival of other bacteria, how do mycoplasmas manage in the absence of this structure? Apparently, they compensate for the absence of a cell wall by incorporating sterols into their cytoplasmic membranes and by the presence of glycoproteins on the cell surface. Both of these may help to stabilize the cells. They also have an unusual cytoskeleton that may contribute to stability.

Fig. 6 Model of *F. johnsoniae* gliding. Gld proteins in the cell envelope form the PMF-powered rotary motors that are attached to the cell wall and propel adhesins such as SprB and RemA along looped helical tracks on the cell surface. The action of the motors on adhesins that are attached to the substratum results in forward movement and rotation of the cell. Two rotary motors are shown. In the model shown, rotation of one motor propels a baseplate carrying SprB and RemA adhesins and delivers it to the next motor. From McBride, M. J. and Nakane, D. (2015). *Flavobacterium* gliding motility and the type IX secretion system. *Current Opinion in Microbiology* **28**, 72–77.

The mycoplasmas and related bacteria have evolved several novel mechanisms for cell movement. Most common is mycoplasma gliding. This involves the movement of cells over surfaces. The cells are often flask shaped, comprised of the cell body, a thinner neck region, and a head region (Fig. 7). A complex cytoskeleton that is especially evident in the neck region is presumably responsible for this shape. Gliding cells always migrate toward the head. A clever experiment conducted by Uenoyama and Miyata in 2005 demonstrated that ATP is the energy source for this movement. They treated motile *Mycoplasma mobile* cells on a glass slide with detergent resulting in leakage of the cytoplasmic contents and formation of cell “ghosts.” These ghosts failed to move. However, addition of ATP resulted in the immediate resumption of gliding motility. Apparently the remaining cytoskeletal and cell surface components of the motility machinery remained functional in the dead cell “ghosts,” and only required addition of their energy source to resume active movement.

Genetic, biochemical and microscopic studies of *M. mobile* identified the cell surface proteins required for motility. Three large proteins (Gli123, Gli349, and Gli521) appear to form the external motility machines that may function as “legs” (Fig. 7). These legs were found primarily in the neck and head region of the cell. ATP hydrolysis in the cytoplasm is thought to cause conformational changes to cytoskeletal proteins that in turn push or pull on the many legs, resulting in the “centipede-like” walking of the mycoplasma cells. It remains unclear if the other gliding mycoplasmas, such as *Mycoplasma pneumoniae*, move in the same way. The surface proteins of *M. mobile* are not conserved in the other gliding mycoplasmas. *M. pneumoniae* may use a similar form of movement with other proteins replacing those of the *M. mobile* legs, or it may use its cytoskeleton and cell surface components to move by a different mechanism. One such proposed mechanism is repeated contraction and expansion of the cytoskeleton to

Fig. 7 “Centipede” model for *Mycoplasma mobile* gliding motility. The cartoons represent a *M. mobile* cell (left) and the cell-surface motility proteins (right). The “neck” region of the cell surface has many protein “legs” (purple). These are associated with a cytoskeletal structure on the inside of the cell (blue). This is sometimes called a “jellyfish structure” because it resembles a jellyfish with the body (“bell”) at the head of the cell and the tentacles trailing behind. ATP hydrolysis in the cytoplasm is thought to result in conformational changes to the legs (stroke), resulting in cell movement. The legs repeat this process and alternate between sticking to the substratum and releasing to allow the cell to essentially “walk.” From Nan, B. and Zusman, D. R. (2016). Novel mechanisms power bacterial gliding motility. *Molecular Microbiology* **101**, 186–193.

shorten and lengthen the cell respectively, resulting in “inchworm” like movement. Additional studies are needed to determine if there is a conserved motility mechanism shared by all gliding mycoplasmas.

The gliding mycoplasmas move over surfaces, but some other mollicutes evolved novel mechanisms to swim. Members of the genus *Spiroplasma* are long, slender, spiral-shaped cells that swim rapidly in viscous, aqueous environments. Spiroplasmas are common insect and plant pathogens. Unlike the similar looking spirochetes, which have flagella embedded in their cell envelopes, the spiroplasmas lack flagella or other obvious motility organelles. Like other mollicutes, they also lack cell walls. Electron microscopy studies revealed the presence of a prominent cytoskeletal system in *Spiroplasma* cells that confers the spiral shape and is also thought to be responsible for movement. The cytoskeleton filaments may function as a contractile linear motor. Conformational changes of components of the cytoskeletal filaments result in “kinks” that progress from one end of the cell to the other. These moving kinks are thought to push the surrounding fluid toward the back of the cell and thus propel the cell forward. Evolution of the unusual and diverse mollicute motility systems, not shared with other bacteria, may have required release from the constraints of the semirigid peptidoglycan layer that encases other bacteria.

Cyanobacterial Gliding Motility: Pili and Polysaccharides

Cyanobacteria (previously called “blue-green algae”) are bacteria that carry out oxygenic photosynthesis. The cyanobacteria invented this process billions of years ago, and today's plants owe their ability to carry out photosynthesis to these bacterial metabolic pioneers. Active motility is common among cyanobacteria, but flagella are absent.

In 1803 Jean-Pierre Vaucher in his “Histoire des conferves d’eau douce” documented the rapid movement over surfaces of filamentous cyanobacteria. These movements are still easily observed today by light microscopic examination of samples from natural environments such as pond water. In the 1900s experiments were performed to understand the mechanism of this movement. Gliding cyanobacteria secrete polysaccharides, and some evidence pointed to this secretion as the propulsive force. However, it was never completely certain if the polysaccharides left behind the cell had caused the movement, or if they had just been deposited as the cells were propelled by another mechanism. Other proposed models involved the generation of waves in the cell surface, perhaps involving the action of contractile filaments in the cell.

Genetic experiments conducted in the 1990s demonstrated that the unicellular cyanobacterium *Synechocystis* sp. PCC 6803 uses type IV pili to move over surfaces (Fig. 8). This is thought to involve extension and retraction of pili, as described above for bacterial twitching motility. In contrast, the mechanism of gliding of filamentous cyanobacteria remained mysterious until very recently. However, it is now clear that the gliding filamentous cyanobacterium *Nostoc punctiforme* moves by a modification of the mechanism used by single-celled cyanobacteria: type IV pilus extension and retraction. *N. punctiforme* grows as long filaments that consist of many cells linked together like beads in a chain. The long vegetative filaments are nonmotile. Under certain conditions shorter filaments (hormogonia) are produced that actively move over surfaces. Genetic analyses revealed that mutations in genes involved in synthesis or function of type IV pili resulted in loss of motility. Microscopic analysis of cells with fluorescently labeled pilin protein indicated that the pili extend from between the junctions of the individual cells of the filament, and suggested that pilus retraction pulls the entire filament across the surface. Polysaccharides also appear to be involved in this process since mutations in genes involved in polysaccharide synthesis also compromised motility. The polysaccharides may coat the substratum and enhance the function of pili by providing a point of attachment for the pili or by altering the friction between the cell and substratum to facilitate pilus-mediated movement. Genome analyses revealed that genes associated with type IV pilus assembly and function are also found in many other filamentous gliding cyanobacteria. Additional experiments are needed to determine if filamentous cyanobacteria have evolved any other gliding mechanisms, such as those postulated to involve propulsion by polysaccharide secretion or by generation of cell-surface waves.

Fig. 8 Type IV pilus-mediated motility over surfaces of unicellular (*Synechocystis* sp. PCC6803, left) and filamentous (*N. punctiforme*, right) cyanobacteria. Movement of *Synechocystis* is similar to twitching motility of other bacterial cells, with assembly of pili, attachment to a surface, and retraction resulting in cell movement. Movement of *N. punctiforme* filaments is a slight variation of this process, with pili extending from locations near each cell junction of the filament. Polysaccharides secreted by *N. punctiforme* also play a role in motility, by either providing a point of attachment for the pili or by decreasing friction to allow the cell filaments to be pulled over the surface.

Gliding cyanobacteria control their movements using proteins that are related to those that control chemotaxis of flagellated bacteria. Both chemotaxis (migration in chemical gradients) and phototaxis (migration toward optimal light conditions) have been observed. Cyanobacterial phototaxis is remarkable in many ways. The individual spherical cells of phototactic *Synechocystis* cells function much like an eyeball to focus light on a single region of the cell, enabling these simple bacteria to identify the location of the light source and migrate directly toward or away from it as appropriate. Some filamentous cyanobacteria have the remarkable property that exposure of one end of a filament to light almost instantaneously alters the movement of the entire filament. How cells of the filament that are not directly exposed to the light source respond is not entirely understood.

Cyanobacterial Nonflagellar Swimming Motility

In the 1980s a novel form of bacterial motility was observed by Waterbury and colleagues in some strains of unicellular marine cyanobacteria belonging to the genus *Synechococcus*. These bacteria actively swim but they lack flagella. Microscopic observation and genome analyses revealed the absence of flagella and of the genes needed to construct flagella. Cells rotate as they swim and the sodium gradient across the cytoplasmic membrane is required for movement. The use of a sodium gradient rather than the more common proton gradient to power a motility machine is not unique to swimming cyanobacteria. Some flagellated marine bacteria also use this sodium motive force instead of a PMF to power their flagella. Large cell surface proteins (SwmA, SwmB) that are involved in motility have been identified by genetic and molecular analyses, but the mechanism of cyanobacterial swimming motility remains a mystery today. Electron microscopic studies revealed the presence of numerous thin structures (spicules) extending from the surface of cells of at least some strains of these bacteria, and these may have a role in movement. One model for cyanobacterial swimming involves generation of cell surface waves that progress from the front to back of the cell resulting in cell movement. These waves might be amplified by the large cell surface proteins and spicules mentioned above. Such waves could be generated by contraction and expansion of structures in the periplasm. Alternatively, motors in the cytoplasmic membrane may propel periplasmic cargo along a helical path to result in the surface waves, as has been suggested for *M. xanthus* gliding above. Additional studies will be needed to determine the exact mechanism of cyanobacterial swimming motility.

“Passive” Movement

The active motility processes described above all require a continuous supply of metabolic energy in the form of ATP or of ion gradients across the cytoplasmic membrane, such as the PMF. Several other forms of bacterial cell movement are less directly connected to such energy sources. These include sliding of cells in a growing colony, and the use of gas vacuoles to position cells optimally in the water column.

Sliding motility is a form of “passive” motility over surfaces. These bacteria produce surfactants that are important in this process. As cells grow and divide to form colonies, the pressures that build up in the crowded colony result in sheets of cells sliding away from the raised colony center. The bacteria form spreading colonies that superficially resemble those of gliding bacteria, but the individual cells lack the ability to move under their own power. Rather, they move when they are pushed by the other growing cells of the colony.

Gas vacuoles are found in some aquatic bacteria and archaea. They are particularly common in aquatic cyanobacteria. Gas vacuoles are comprised of multiple gas vesicles. Each gas vesicle is a protein shell filled with gas. The gas that fills the vesicles has similar composition as the surrounding atmosphere. Gas vesicles and gas vacuoles are not enclosed by lipid membranes. The presence of gas vacuoles alters the buoyant density of the cell, and allows cells to float higher in the water column. The balance between production of gas vacuoles and production of more dense cell components determines how rapidly the cells rise or fall in the water column. Cells with gas vacuoles can travel significant distances to reach a favorable zone in the water column. For photosynthetic bacteria, this may be the region where the light intensity is optimal.

“Parasitic” Movement

One form of nonflagellar bacterial motility occurs only within eukaryotic cells. These intracellular pathogens include Gram negative (e.g., *Shigella dysenteriae*) and Gram positive (e.g., *Listeria monocytogenes*) bacteria. What these bacteria have in common is the ability to enter the eukaryotic host cell cytoplasm and the production of a protein on their cell surface that facilitates the assembly of filaments of host cell actin. The actin-nucleating proteins are usually located at one pole of the bacterial cell. Assembly of actin filaments prevents backward movement and thus facilitates forward movement of the bacterium within its host cell. It can also result in migration of bacteria into neighboring cells, resulting in spread of the infection within the host. The movements rely on host cell actin and thus can only occur as part of this parasitic relationship. These bacteria can also grow outside of the host cell and some of them exhibit other forms of motility such as flagellar-based swimming under those conditions.

Summary

The most well understood form of bacterial movement involves rotation of flagella but bacteria have evolved numerous other ways to move. Many of these are specialized for movement over surfaces, and include the pulling of cells by pilus retraction (twitching motility), and various forms of gliding motility that involve either conveyor belt-like motion as a result of movement of proteins along cytoskeletal or cell-surface tracks, or the centipede-like motion of mycoplasmas. Some of these are powered by ATP hydrolysis (twitching motility, mycoplasma gliding) whereas others use the proton gradient across the cytoplasmic membrane (myxobacterial gliding and *Bacteroidetes* gliding). Other bacteria lack flagella but move through aqueous environments. Spiroplasmas and some marine cyanobacteria actively swim using novel and still poorly understood machines. Other bacteria migrate vertically in a water column using gas-filled protein shells to alter their buoyant density, or make use of host cell proteins to move within the cytoplasm of a eukaryotic cell. In spite of decades of research the mechanisms underlying many of these forms of bacterial motility are incompletely understood. Future research will likely reveal additional surprises regarding these diverse nonflagellar bacterial motility systems.

Glossary

Acidogenic Refers to bacteria that produce acid from metabolism of sugars.

Aciduric The ability to withstand conditions of low pH.

Acquired salivary pellicle A layer of proteins and glycoproteins of salivary origin that covers the surface of teeth.

Calculus A mineralized deposit that accumulates on the surface of teeth, usually close to the gum margins.

Coaggregation Cell–cell recognition between genetically distinct cells mediated by complementary surface molecules on the two or more partner cell types.

Commensalism A symbiotic relationship between two organisms of different species in which one partner derives a benefit and the other suffers no harm.

Dental plaque The biofilm on tooth surfaces.

Gingival crevice The narrow space below the gumline between the tooth and the gum tissue (gingiva).

Gingival crevicular fluid (GCF) A fluid derived from serum that seeps across the epithelial barrier into the gingival crevice.

Oral biofilm The multispecies community of microorganisms and associated extracellular material that is present on the surface of teeth or soft tissues in the mouth.

Periodontium Tissues and supporting structures that hold a tooth in place.

Phylotype An evolutionarily related group of organisms. Phylotypes of oral bacteria are typically defined as sharing $\geq 99\%$ sequence identity in the gene encoding the 16S subunit of ribosomal RNA.

Subgingival plaque Plaque that develops on tooth surfaces below the gumline and tends to be anaerobic.

Supragingival plaque Biofilm on teeth above the level of the gums.

Abbreviations

AI-2	Autoinducer-2
CSP	Competence-stimulating peptides
GCF	Gingival crevicular fluid
IE	Infective endocarditis
IL-1 β	Interleukin-1 β
LDL	Low-density lipoprotein
PRG	Proline-rich glycoprotein
PRP	Proline-rich protein
RANKL	Receptor activator for nuclear factor κ B ligand
RPS	Receptor polysaccharides
S-IgA	Secretory immunoglobulin A
TLR	Toll-like receptor
TNF- α	Tumor necrosis factor- α
VAP	Ventilator-associated pneumonia
VEGh	Von Ebner glands protein

This article is an update of P.E. Kolenbrander, N.S. Jakubovics, G. Bachrach, Oral Microbiology, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 566–588.

Human Oral Microbiology

Like the vast majority of microbial populations in nature, microbial inhabitants of the oral cavity are predominantly found in surface-attached multispecies communities. However, the warm, moist character of the mouth combined with the relatively open access to the wider environment presents a unique niche for microorganisms. In fact, the oral cavity is a heterogeneous environment that contains numerous different surfaces for bacterial colonization, including gums, teeth, cheeks, tongue, and palate. Oxygen levels are not constant and range from fully aerobic in the outer layers of dental plaque to levels that are low enough to support the growth of strict anaerobes around the circumvallate papillae towards the back of the tongue and in deeper areas of dental plaque both above (supragingival) and below (subgingival) the gumline (Allaker et al., 2008; Hanioka et al., 2000). The microbial species diversity in the mouth is influenced by the presence of disease. For example, the bacterially produced acid responsible for dental caries selects for organisms that can tolerate low pH (Richards et al., 2017). Another major class of oral pathology is inflammatory gum disease, known as gingivitis (bleeding gums) or periodontitis. If left unchecked, periodontal disease can lead to the formation of pockets of up to 8–10 mm depth below the gumline and adjacent to the teeth. These periodontal pockets are protected from the flow of saliva and movement of the tongue, and are bathed in gingival crevicular fluid (GCF), an exudate derived from serum. The microflora in periodontitis is distinct from that in biofilms at other locations in the oral cavity (Meuric et al., 2017). Thus, oral surfaces whether they are hard (tooth) or soft (epithelial) are colonized by bacterial communities that differ and are site-specific (Eren et al., 2014).

Our understanding of oral microbiology has been greatly impacted by the “-omics” revolution that began in the 1990s (Nascimento et al., 2017). This term relates to the development of new methodologies that enabled the simultaneous analysis of large numbers of targets such as genes, proteins, metabolites or cells rather than focusing on one at a time. These methods have been particularly beneficial for complex systems such as oral biofilms, where there may be hundreds of different microbial species all metabolizing in different ways and each interacting with neighboring microbes or the host. The overall species composition in such an environment is known as the microbiome. Each member of this microbial community brings its own genome, the total genetic content of the cell. The prefix “meta-” is used to denote the content within a complex population rather than one individual, and thus the metagenome refers to the total genetic content of a mixed microbial population. The functions of oral microbial communities, and the ways in which they respond to individual stimuli or during the transition from health to disease, can be monitored by studying the metatranscriptome (messenger RNA transcripts present in the microbial cells), metaproteome (all the different proteins present), or metabolome (metabolites that have been produced). Of course, all of these microbial factors may be studied in relation to the host genome, transcriptome or proteome, to understand how microbes and the host interact with one another. Overall, these studies have begun to reveal how the microbial population changes from a health-associated state to a dysbiotic state in diseases such as dental caries, and how treatment can potentially recover the system to a stable “healthy” state (Gomez and Nelson, 2017; Nascimento et al., 2017).

In total, more than 700 phylotypes of bacteria have been detected in the human mouth, representing at least 300 different species. The most abundant genera in health include *Streptococcus*, *Haemophilus*, *Prevotella* and *Veillonella* (Human Microbiome Project Consortium, 2012). Viruses are also present, and the majority of these are bacteriophage that target a variety of different oral bacteria (Edlund et al., 2015). A relatively small number of fungi are found in oral biofilms (Diaz et al., 2017). Of these, *Candida* spp. are by far the most important in terms of their potential to cause disease. With just a few notable exceptions, oral diseases are caused by the combined actions of multiple species of microorganisms in polymicrobial communities. The great challenge for oral microbiologists is to understand how these microbes interact with one another and with the host in health and disease.

Characteristics of the Oral Environment

Host Surfaces Available for Microbial Colonization

Epithelial cells are constantly shed from soft tissues (desquamation) along with any bacteria attached to them. According to estimates, cells in the outer layer of epithelial surfaces in the oral cavity are shed as rapidly as every 3 h (Dawes, 2003). Therefore, bacteria that colonize oral epithelia must continually reinfect the surface to avoid being lost. Escaping detachment is also a problem for bacteria on the tooth surface because saliva shear and oral hygiene procedures such as tooth brushing remove attached bacteria. Gum margins and cracks and fissures in the teeth constitute natural areas of protection for bacteria. Artificial havens for bacteria are provided by orthodontic appliances such as braces, which often leave exposed areas of enamel that are difficult to access with a toothbrush. Areas that have not been fully cleaned act as reservoirs for a fresh supply of microorganisms to recolonize the tooth surface. Although new species are constantly introduced into oral biofilms, some strains may persist in a person’s mouth for several months at least (Haraldsson et al., 2004; Kirchherr et al., 2005). Clearly, such strains have highly effective colonization and commensal mechanisms that prevent the strains from being cleared during oral hygiene procedures.

Mucosal surfaces

In fully dentate adults, teeth provide approximately 20% of the total surface area in the oral cavity and the remainder is soft tissue (Collins and Dawes, 1987). Keratinized epithelium is present in areas that are subject to high compression or friction such as the hard palate and the exposed surface of the gingiva. In contrast, the mucosa of areas that require flexibility such as the cheeks, floor

of the mouth, and the ventral surface of the tongue contain nonkeratinized epithelium. Certain species of streptococci preferentially attach to either keratinized or nonkeratinized tissues *in vitro* (Sklavounou and Germaine, 1980), and streptococci belonging to the *S. mitis/oralis/infantis* cluster are more abundant on keratinized oral epithelial tissues *in vivo* (Eren et al., 2014). However, in general, keratinized gingiva harbor a distinct population from other keratinized oral epithelial surfaces, indicating that other characteristics of oral epithelia are also important for directing microbial colonization. Interestingly, the microbial population on palatine tonsils is more similar to that on mineralized tissues, and subgingival dental plaque in particular, than on other epithelial surfaces (Eren et al., 2014). This may be a result of the reduced oxygen tension in the tonsillar crypts, which will select for anaerobic species. Anaerobic microorganisms on the tongue dorsum play an important role in generating volatile sulfur compounds and other malodorous chemicals that are associated with halitosis (bad breath) (Yang et al., 2013). It should be noted that the distribution of anaerobes on the tongue dorsum is uneven (Allaker et al., 2008), and the overall microbial population across the tongue dorsum is not significantly different from other oral epithelia (Eren et al., 2014). The microbial population on the tongue is dynamic and the relative abundances of the major species present changes significantly from week to week (Flores et al., 2014; Hall et al., 2017; Mark Welch et al., 2014). Despite these changes, the most abundant species, the “core microbiome,” remain detectable on the tongue for weeks or months, whereas rare species in the community are frequently lost and replaced by others (Hall et al., 2017).

Mineralized tissues

The inner regions of teeth are composed of a central core of connective tissue (dental pulp) surrounded by a mineralized tissue, dentine (Fig. 1). At the roots, the dentine is enclosed within a thin layer of cementum. The crown of the tooth contains a hard enamel exterior and provides strong protection against oral bacterial challenge. Enamel is the hardest biological tissue and is almost entirely mineral in content. More than 95% of the mass of enamel is calcium hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) and the rest is organic material and water. The enamel layer is thickest at the occlusal part of the tooth crown, and becomes very thin toward the gingival margin. Dental caries is characterized by a localized loss of the outer mineral layer of the teeth caused by acids derived from bacterial sugar metabolism. Caries most commonly affects enamel, but root dentine can also become demineralized if it is exposed by recession of the gums (Takahashi and Nyvad, 2016). In the absence of an intact outer tooth layer, bacteria may invade the dentine and often cause painful endodontic infections.

Saliva is supersaturated with respect to calcium hydroxyapatite, and this prevents net demineralization of enamel in the absence of high concentrations of acids. However, large amounts of calcium phosphates in saliva can lead to the accumulation of unwanted mineral deposits (calculus) on tooth surfaces where plaque exists. Dying bacterial cells may contribute to calcification by accumulating minerals and ions, which then precipitate intracellularly (Moorer et al., 1993). Extensive calculus at the gingival margin irritates the gum tissue and correlates with gingival recession. Accumulation of subgingival calculus coincides with periodontal disease and, at least in some cases, calculus contributes to disease progression. Effective control of dental plaque is therefore fundamental for maintaining healthy enamel surfaces.

In health, many of the microorganisms present in dental plaque can also be detected in saliva or on oral epithelial surfaces (Human Microbiome Project Consortium, 2012). This is not surprising since saliva is responsible for transporting bacteria to tooth surfaces, and the majority of microbial cells in saliva are attached to desquamated epithelial cells (Dawes, 2003). Epithelial cells are commonly found in dental plaque, and it is likely that many bacteria reach the tooth surface by “hitchhiking” on host cells (Tinanoff and Gross, 1976). Nevertheless, the environment of the tooth surface selectively enriches certain bacteria and snapshots of the microbial population at different sites in the human mouth indicate that the microbiota of supra- and sub-gingival dental plaque is distinct from other sites in the mouth (Eren et al., 2014). For example, *Streptococcus gordonii*, *Streptococcus sanguinis*,

Fig. 1 Basic structure of a tooth and common areas of biofilm formation. Supragingival plaque forms on enamel above the gumline. Subgingival plaque develops between gum tissue (gingiva) and the hard tissue of the tooth (enamel or cementum). The underlying structures of the tooth are not normally exposed to bacteria in health. However, dental caries can lead to invasion of bacteria through the enamel into dentine and eventually to the pulp chamber.

Corynebacterium matruchotii and *Corynebacterium durum* are enriched in dental plaque, whereas *Streptococcus infantis* and *Streptococcus salivarius/veibularis* are enriched on soft tissue surfaces (Eren et al., 2014; Mark Welch et al., 2016).

Artificial (synthetic) surfaces

Dental intervention procedures introduce a variety of materials into the mouth, which may be retained for months or, in many cases, years. These materials provide new surfaces for microbial colonization and frequently affect the surrounding tissues.

Restorations of damaged teeth form a major component of modern dentistry. The widespread use of silver-based amalgam alloys as filling materials can be traced back to the early decades of the nineteenth century. In many Western countries, amalgam restorations are gradually being replaced by composite resins and glass ionomer cements, which do not contain mercury and are aesthetically more pleasing. The occurrence of caries adjacent to the filling material, termed “secondary” or “recurrent” caries, is a significant risk factor for failure of the restoration. One approach to limiting secondary caries has been to include fluoride in the matrix of glass ionomer cements (Chau et al., 2015). The fluoride is released slowly over a period of weeks. Fluoride-releasing formulations inhibit the growth of a variety of bacteria *in vitro*. However, the presence of salivary flow appears to limit the antibacterial properties of these resins and there is little evidence that the current formulations provide long-term protection against secondary caries *in vivo* (Wiegand et al., 2007).

Signs of caries are a common problem during orthodontic treatment. A survey of children in England, Wales and Northern Ireland conducted in 2013 found that 9% of 12-year olds and 18% of 15-year olds wore orthodontic appliances (braces) (Rolland et al., 2016). Fixed braces are bonded to enamel surfaces and are typically worn for 18–24 months. These devices impede salivary flow and interfere with conventional oral hygiene procedures. White spot lesions, which occur at the early stages of caries, are commonly reported in the areas adjacent to the bonding material. In one study, around 40%–50% of buccal tooth surfaces that had been fitted with fixed braces (multibracket appliances) were found to have developed white spot lesions upon removal of the appliance (Beerens et al., 2015). Typically, the lesions do not progress once the orthodontic appliance is removed. However, remineralization of the lesions occurs slowly, and the consequences of microbial activity during orthodontic treatment therefore remain visible for many years.

The elimination of pathogenic microorganisms is a significant challenge during more invasive dental surgery. Where whole teeth are lost, restorations require the insertion of implants into the alveolar bone. Titanium is almost exclusively used for implants because of its ability to adhere and integrate into regrowing bone. In approximately 40% of implants, a gradual infection and inflammation will result in loss of supporting alveolar bone (peri-implantitis) (Derks and Tomasi, 2015; Derks et al., 2016), which may occasionally lead to failure of the implant (Chrcanovic et al., 2014). Lesions in the mucosa surrounding the implant (peri-implant mucositis) are also common, although it is difficult to estimate the prevalence due to the lack of a consensus for diagnostic criteria between different studies (Derks and Tomasi, 2015; Figuero et al., 2014). Peri-implantitis and peri-implant mucositis are essentially the same disease, distinguished only by a higher degree of alveolar bone loss in peri-implantitis patients. The etiology of peri-implantitis is thought to be similar to that of periodontal disease and previous experience of periodontal disease is a significant risk factor for implant failure (Monje et al., 2014). Therefore, a periodontal care program may be beneficial for patients receiving dental implants.

Where it is impractical to fix artificial dentition in the mouth, tooth function may be restored by wearing dentures. The use of dentures introduces a relatively large surface area into the mouth for prolonged periods, and dentures are thus susceptible to microbial colonization. The constant contact between denture biofilms and mucosal epithelia frequently results in infection, known as denture stomatitis. In epidemiological studies, the prevalence of denture stomatitis amongst denture wearers ranges from 15% to 70% (Gendreau and Loewy, 2011). *Candida* spp. are considered the primary etiological agents of denture stomatitis. However, as with other oral diseases of microbial origin, it is likely that other microorganisms contribute to pathogenesis, and indeed the microbiome associated with denture stomatitis is extremely complex (Shi et al., 2016). Reports of denture stomatitis in the absence of *Candida* spp. exist, and there is no evidence that antifungal treatments improve clinical outcomes (Emami et al., 2014). Therefore, further investigations on the etiology of denture stomatitis are required in order to identify improved approaches for treating the disease.

Body Fluids

Saliva

Saliva has a wide range of functions, many of which are related to protection against oral microorganisms. However, it is important to note that many oral microbes are well-adapted to exploit saliva as a key source of nutrients (Jakubovics, 2015). In fact, saliva is the most important nutrient source during the formation of supragingival dental plaque. It is only once plaque matures that nutrients from the host diet start to have a significant impact on the function of dental plaque (Bowden and Li, 1997). In some situations, components of saliva can coat surfaces, where they may promote adhesion and colonization of microorganisms. The roles of saliva in promoting and inhibiting microbial adhesion are discussed in detail in the section *Microbial Interactions in Oral Biofilms*.

The importance of saliva in controlling infections is apparent from patients suffering chronic hyposalivation, which is a side effect of many drugs, autoimmune disorders such as rheumatoid arthritis and Sjögren’s syndrome, and of radiotherapy treatment for head and neck cancers (Millsop et al., 2017). These patients have an increased propensity for caries, periodontal disease, and opportunistic infections such as candidiasis (Billings et al., 2017; Chapple et al., 2017). Caries associated with hyposalivation has an

Fig. 2 Salivary components that influence microbial activity. Bactericidal (e.g., lysozyme, histatins, defensins, LL-37), fungicidal (chitinase, histatins, defensins), and antiviral (VEGh, mucins, cystatins, defensins) compounds reduce the overall microbial load in the mouth. Microorganisms are aggregated by Gp340 or mucins, and this is thought to aid their removal by swallowing. However, a number of bacteria can adhere to these same compounds when they are immobilized on surfaces leading to the initiation of a microbial biofilm. Bicarbonate plays a key role in buffering saliva and preventing acid demineralization of enamel. Other inorganic (Ca²⁺, phosphate) and organic (mucins, PRPs, statherin) components of saliva help maintain a healthy mineral content in enamel.

unusual pattern and frequently occurs at the cervical margin, the area where the cementum of the tooth root meets the enamel of the crown (Boutsi et al., 2000; Silva et al., 2009). The infection control properties of saliva can be attributed to a number of factors that broadly group into (1) antimicrobial (bacteriostatic or bactericidal) molecules, (2) adhesion inhibitors, and (3) protection and maintenance of epithelial barriers (Fig. 2).

Whole saliva is a mixture of the products of all salivary glands together with proteins and carbohydrates of bacterial origin, remnants of foodstuffs, cellular debris, and serum exudate from gingival crevicular fluid (GCF). High concentrations of serum proteins such as albumin are indicative of gingival inflammation and leakage through the epithelial barrier (Henskens et al., 1993). The major components of saliva, more than 100 proteins and glycoproteins in total, are actively secreted by three major pairs of glands (parotid, sublingual, and submandibular) and several smaller glands. The composition of whole saliva depends to a great extent on the relative activities of the serous (parotid) and seromucous (submandibular/sublingual) glands (Jasim et al., 2016). The parotid glands are the largest salivary glands and, following mechanical or acid stimulation, contribute approximately 50% of the volume of secreted saliva in the mouth (Proctor, 2016). Approximately 70% of proteins in parotid saliva are proline-rich proteins (PRPs), a family of polypeptides that contains 35%–40% proline residues, and most of the remainder is α -amylase (Bennick, 1982). In the absence of stimulation, around two-thirds of whole saliva is derived from the submandibular gland. Secretions from this, and the sublingual gland, contain mucins and are consequently more viscous and viscoelastic than parotid saliva (Park et al., 2007; Zussman et al., 2007).

Mucins play a key role in protecting oral tissues from desiccation, mechanical insults, and microbial challenge. Human saliva contains two distinct classes of mucins, MG1 and MG2, which are produced by the MUC5B and MUC7 genes, respectively. Together these form the major component of the “mucosal pellicle” that covers oral epithelial surfaces (Hannig et al., 2017; Helmerhorst and Oppenheim, 2007). MG1 belongs to the classical mucins that cover epithelial surfaces throughout the human body. More than 80% of MG1 mucin is carbohydrate, and monomers of MG1 are disulfide-linked in a long thread-like structure with a total $M_r > 1000$ kDa (Thomsson et al., 2005). Even at low concentrations, MG1 forms a viscoelastic gel (Raynal et al., 2002; Wickström et al., 1998). In contrast, MG2 is a relatively small (150–200 kDa) molecule with low viscoelastic properties. The carbohydrate content of MG2, approximately 68% of the total mass, is lower than that of MG1. In addition, the carbohydrate side chains of MG2 are relatively short and uniform. Approximately 80% of the MG2 carbohydrates are Gal β 1 $\rightarrow$ 3GalNAc with or without a terminal fucose or sialic acid residue (Nieuw Amerongen et al., 1995). Whereas MG1 has only been shown to bind a few species of bacteria such as *Haemophilus parainfluenzae* and *Helicobacter pylori*, MG2 appears to have a significant role in binding a broad range of

microorganisms (Frenkel and Ribbeck, 2015a, b and see below). Bacterial adhesion is mediated by protein and by carbohydrate structures of MG2. Although MG2 mucin is present in the mucosal pellicle, it is almost absent from the pellicle on tooth enamel (Hannig et al., 2017). Therefore, bacterial binding by MG2 may help to sequester bacterial cells away from the tooth surface. Mucin MG1 has also been shown to keep *Streptococcus mutans* in a planktonic state, in this case by repelling it from adhering to surfaces (Frenkel and Ribbeck, 2015a, b).

Preventing dissolution of tooth enamel by microbially produced acid requires strong buffering capacity in saliva and supersaturation with calcium and phosphate ions. Buffering is provided primarily by bicarbonate, which can reach concentrations in excess of 25 mM under stimulated conditions (Neyraud et al., 2009). Maintenance of calcium and phosphate is facilitated by acidic PRPs, histatin and statherin (Tamaki et al., 2002). These molecules bind calcium ions and inhibit precipitation of calcium phosphates.

Removal of specific acidogenic bacteria may be another strategy for protection against dental caries. Strains of *S. mutans*, a species strongly associated with dental caries, are aggregated by a salivary component termed salivary agglutinin, which has now been identified as glycoprotein gp340 (Jakubovics et al., 2005; Loimaranta et al., 2005). Aggregation of oral bacteria enhances clearance from the oral cavity by swallowing or phagocytosis (Itzek et al., 2017). In contrast, adhesion of *S. mutans* to gp340 adsorbed on enamel surfaces will promote colonization, as discussed in the following text. A number of other salivary molecules have been implicated in adherence and/or aggregation of oral bacteria, including PRPs, statherin, α -amylase, and secretory immunoglobulin A (S-IgA) (Rudney, 2000). The impact of adhesion versus aggregation on the colonization of tooth surfaces by bacteria is discussed in more detail below.

Saliva contains several products that kill or restrict growth of microorganisms. For example, cystatins are cysteine proteinase inhibitors that have been shown to inhibit growth of the periodontal disease-associated species *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* (Blankenvoorde et al., 1998; Ganeshnarayan et al., 2012) and to possess potent antiviral activities (Bjork et al., 1990; Korant et al., 1985). Saliva also contains another class of cysteine proteinase inhibitor, the salivary lipocalin von Ebner glands protein (VEGh), which may play similar roles in inhibiting replication of bacteria and virus particles (van't Hof et al., 1997).

Bacteria and fungi require certain essential nutrients such as metal ions for growth, and saliva, like other body fluids, contains proteins that sequester metals. Lactoferrin is present in saliva, milk, and tears and binds iron with high affinity ($K_D \sim 10^{-20}$ M) (Rosa et al., 2017). Lactoferrin has a broad spectrum of antimicrobial properties against bacteria, fungi, and viruses, and not all of these are attributable to its ability to deplete free iron. It has been shown that lactoferrin binds cell walls of Gram-negative bacteria and *Candida* spp., and this appears to interfere with the integrity of the cell membrane (Nikawa et al., 1993). Manganese and zinc ions are important components of many bacterial enzymes. Chelation of Mn^{2+} and Zn^{2+} by calprotectin inhibits growth of *Staphylococcus aureus* in abscesses (Corbin et al., 2008). Calprotectin in saliva is derived primarily from GCF and epithelial cells and is upregulated in gingival inflammation, candidiasis and in Sjögren's syndrome (Farina et al., 2012; Sweet et al., 2001). Interestingly, polymorphisms in the calprotectin gene have been correlated with susceptibility to chronic periodontitis (Sun et al., 2011). Calprotectin expression by oral epithelial cells protects against *P. gingivalis* infection *in vitro* (Nisapakultorn et al., 2001). Therefore, metal binding proteins such as lactoferrin and calprotectin appear to play important roles in host defenses against oral diseases.

Microbicidal enzymes are important components of saliva. Under aerobic conditions, salivary lactoperoxidase enhances oxidative killing of microorganisms by converting thiocyanate and hydrogen peroxide (H_2O_2) to the strongly antibacterial molecule hypothiocyanite ($OSCN^-$). Certain oral streptococci secrete H_2O_2 during growth and there is some evidence that H_2O_2 -producing streptococci such as *S. mitis* and *S. sanguinis* are better able to recover after exposure to $OSCN^-$ than *S. mutans* and *S. salivarius* strains that do not secrete H_2O_2 (Carlsson et al., 1983). $OSCN^-$ is believed to cause cellular damage by oxidizing sulfhydryl groups in intracellular proteins (Nagy et al., 2009). In contrast to H_2O_2 , $OSCN^-$ does not cause DNA damage and is not thought to be harmful for the host cells that produce it. In saliva, uric acid may compete with thiocyanate to inhibit the production of $OSCN^-$ and it is not yet clear whether lactoperoxidase is an important antimicrobial defense mechanism naturally (Seidel et al., 2014). Nevertheless, an H_2O_2 -generating system such as glucose oxidase, lactoperoxidase and thiocyanate has been used in oral care products and shows strong *in vitro* antimicrobial activity in the presence of saliva (Welk et al., 2011).

Lysozyme is present in all major body fluids and has well-characterized antibacterial activity. Lysozyme hydrolyzes glycosidic linkages in the peptidoglycan of some bacterial cell walls, resulting in cell lysis or weakening of the cell barrier. In addition, lysozyme can potentiate nonenzymatic cell degradation in some bacterial species, for example by acting as a cationic antimicrobial peptide (Herbert et al., 2007). Chitinase, which catalyzes the hydrolytic cleavage of chitin, has also been found in saliva (Prodan et al., 2015). Chitin is a component of *Candida* spp. cell walls and chitinase may therefore protect against yeast infections.

Antimicrobial peptides are a key component of innate immunity and it is clear that many peptides produced in saliva have antimicrobial activity. Most work on salivary antimicrobial peptides to date has focused on histatins, a family of neutral or cationic peptides that are rich in histidine residues. At least 25 different histatin peptides have been found in saliva, of which histatins 1 and 3 are encoded by distinct genes and others are generated by proteolysis (Castagnola et al., 2004). Histatins 1, 3, and 5 predominate in parotid saliva (Campese et al., 2009). Histatins are bactericidal against some strains of *S. mutans* and prevent hemagglutination by *P. gingivalis* (Murakami et al., 1992). However, in relation to other antimicrobial peptides throughout the body, the antibacterial properties of histatins are relatively weak. Histatins may be more important in defense against fungal infections because they are potent inhibitors of *Candida* spp. germination and growth (Xu et al., 1991). Human α -

and β -defensins and cathelicidin LL-37 have been identified in saliva: these cationic peptides have broad spectra of antimicrobial properties against fungi, Gram-negative and Gram-positive bacteria, and some enveloped viruses (De Smet and Contreras, 2005). Human β -defensins are expressed in duct cells of salivary glands and in oral epithelial cells (Sahasrabudhe et al., 2000). The α -defensins are expressed in salivary glands and it is likely that they are introduced into saliva by neutrophils that continually migrate across the epithelial barrier (Dale et al., 2006). Neutrophils are also likely to be a significant source of LL-37 in saliva. Individuals with deficiencies in α -defensin and LL-37 levels in neutrophils had no detectable LL-37 in saliva and had severe periodontal disease (Pütsep et al., 2002). In addition, it has been shown that low levels of α -defensins correlate with caries experienced in children (Tao et al., 2005).

Many antimicrobial peptides, including histatins and LL-37, are generated by proteolytic cleavage of larger molecules. The N-terminal regions of lactoferrin and mucin MG2 contain peptide elements that, when synthesized in isolation, display antimicrobial properties against a range of bacteria and fungi (Chapple et al., 1998; Wei et al., 2007). The N-terminal antimicrobial region of lactoferrin, designated lactoferricin-H, is released by pepsin digestion under acidic conditions, a reaction that occurs in the stomach. However, it is not clear whether the N-terminal domains of lactoferrin or MG2 possess antimicrobial activity in saliva. Irrespective of the natural function of these peptides, there is clear potential for exploiting their antimicrobial properties for therapies aimed at oral diseases.

Gingival crevicular fluid

In 1956, while tackling problems related to failures of dental implants in dogs, Neils Brill and Bo Krasse observed that significant amounts of fluid started to ooze from healthy regions of the gingival crevice immediately after drying the entire area (Krasse, 1996). Subsequent work showed that a dye injected into the hind leg of an animal appeared in the gingival crevice within 30 s. The serum-based exudate GCF is also produced in humans and bathes bacteria in gingival crevices and periodontal pockets and seeps gradually into saliva. GCF production is dramatically increased in periodontal disease, and periodontitis treatment protocols can reduce the amount of GCF present. Besides containing serum, GCF contains locally generated degradation/secreted products of tissues and bacteria, inflammatory mediators, and antibodies. Intensive efforts are under way to find diagnostic and prognostic markers of disease in GCF (Kinney et al., 2014).

Microbial Interactions in Oral Biofilms

Acquisition of the Oral Microbiota

Bacterial DNA can be detected in neonates right at the point of birth, and within hours *Staphylococcus* spp. and *Streptococcus* spp. can be cultured (Chu et al., 2017; Nelson-Filho et al., 2013). These genera were shown to be the most abundant over the first 8–21 days of life in a sample of six low birthweight infants (Costello et al., 2013). By 4–8 weeks, streptococci account for 55%–90% of all bacteria in breastfed or formula fed infants, and independent of delivery mode (vaginal delivery or caesarian section) (Al-Shehri et al., 2016; Barken et al., 2008). A study of five edentulous infants with a mean age ~4.6 months found that *Streptococcus* remained the dominant genus prior to tooth eruption and accounted for approximately 60% of oral bacteria (Cephas et al., 2011). Interestingly, many of the species that are commonly found in dental plaque such as *S. sanguinis* and *S. gordonii* (Eren et al., 2014) were present in the saliva of these infants, indicating that the presence of tooth surfaces is not essential for these species to thrive in the oral cavity. Between 3 months and 3 years of age, the species richness (total number of different species present) and the diversity of taxa (a measure that accounts for both the richness and the evenness of taxa) increases significantly (Lif Holgersson et al., 2015). Major events that lead to changes in the infant microbiome are thought to be tooth eruption and weaning. The oral microbiome continues to mature through childhood until at least the age of 18 years (Crielaard et al., 2011; Gomez and Nelson, 2017; Papaioannou et al., 2009).

There is evidence that early acquisition of *S. mutans*, or the presence of increased *S. mutans* load in infancy, is correlated with caries development in children (Lif Holgersson et al., 2015; Straetemans et al., 1998). In adults, *S. mutans* is commonly found in biofilms on enamel and is detectable at low levels in >95% of adults (Lindquist et al., 1989; Lindquist and Emilson, 1990). Culture-based approaches indicated that the acquisition of *S. mutans* occurs at a particular time during childhood (Caufield et al., 1993). This “window of infectivity” was found to occur between 19 and 31 months after birth with the median age for acquiring *S. mutans* being 26 months. Curiously, the median age for tooth emergence is 7.1 months; yet, the window of infectivity for this bacterium appeared to be at least a year later. More recent studies have now shown that the window of infectivity is not absolute. In one cohort of 104 subjects, 12% of infants were found to be colonized by *S. mutans* by just 4–6 weeks (Reed et al., 2014). Although tooth surfaces are clearly not essential for *S. mutans*, it has been demonstrated that there is a correlation between tooth eruption and the acquisition of mutans streptococci (Nelson et al., 2014).

The source of each person's individual strains of bacteria is unknown but the close contact with family members or other caregivers probably influences the species of bacteria that inoculate and colonize the oral cavity. This notion is supported by the studies using *S. mutans*, which is common in adult saliva. Unique patterns of bacteriocin production and sensitivity of isolates of *S. mutans* from mother–infant pairs were very similar, suggesting that intrafamilial transmission is a likely route for establishing the oral microbial populations of children (Berkowitz and Jordan, 1975). More recently, genetic fingerprinting techniques have confirmed that identical strains of *S. mutans* can be found in mothers and their children (Li and Caufield, 1995; Momeni et al., 2016).

Bacteria–Host Interactions

For successful colonization of surfaces in the oral cavity, bacteria must attach to soft or hard tissues, obtain energy from the available nutrients to grow and divide, resist or evade host immune responses, and compete or cooperate with neighboring bacterial cells to establish a stable biofilm community. Much attention has focused on the first step in colonization, bacterial adhesion to host tissues, because this holds great promise for proactive strategies that are aimed at preventing integration of harmful bacteria into oral biofilms and thus avoiding even the early stages of disease. Adhesion is a selective process that involves specific interactions between receptors immobilized on the surfaces of host tissues and adhesive proteins and glycoproteins (adhesins), expressed in the outer layers of oral bacterial cells.

Bacterial colonization of tooth enamel: Adhesion versus aggregation

All tooth surfaces in the oral cavity are coated with a layer of proteins and glycoproteins known as the acquired enamel pellicle (Siqueira et al., 2012). The pellicle starts to form within 1 min of introducing a clean enamel surface into the mouth and reaches equilibrium between dissociation and deposition of material at 90–120 min (Lee et al., 2013). After 2 h, the pellicle consists of a compact basal layer and a globular surface layer (Hannig, 1999). The activity of some enzymes is affected by immobilization on a surface. Nevertheless, it is clear that a wide range of salivary enzymes retain catalytic activity when adsorbed onto calcium hydroxyapatite (Hannig et al., 2005). Accumulation of salivary pellicle on enamel is a process of selective adsorption of salivary components, and the (glyco)protein composition of pellicle is thus distinct from that of unbound saliva. Because of the ubiquitous presence of salivary pellicle, bacteria that attach to teeth do not make contact with the enamel directly, but instead interact with pellicle components.

Investigations on the inhibitory role of S-IgA on adhesion of oral bacteria to enamel surfaces in the early 1970s led Ronald Gibbons and coworkers to propose that aggregation (agglutination) of bacteria might be an active mechanism for clearing bacteria from the oral cavity (Bammann and Gibbons, 1979; Bratthall and Gibbons, 1975). It was suggested that large aggregates coated with S-IgA would be less prone to attach to surfaces than single uncoated bacterial cells, and that aggregates would presumably be removed by swallowing. These seminal studies led to a new way of thinking about oral bacterial adherence as an interplay between factors that promote clearance from the oral cavity (including molecules that cause aggregation of bacterial cells) and components that aid bacterial adhesion to oral surfaces. It is now recognized that the abilities of different host receptors, including S-IgA, to modulate bacterial adhesion and/or aggregation are extremely complex. Like many other salivary proteins, S-IgA is present in both saliva and the acquired salivary pellicle and may therefore inhibit or promote bacterial adhesion, depending on the context (Stiefel, 1976). Bacteria that adhere to salivary pellicle, predominantly the oral streptococci, tend to have multiple specificities for host receptors and it is often difficult to define the roles of individual (glyco)proteins in adhesion (Jakubovics et al., 2005). Furthermore, aggregation may not necessarily lead to clearance from the oral cavity. *In vitro* studies indicated that large aggregates of *Streptococcus* spp. or *Actinomyces* spp. cells have reduced affinity for saliva-coated hydroxyapatite, but that small aggregates of two to three times a single adhering unit actually show enhanced capacity for binding (Liljemark et al., 1981). In many cases, recognition of salivary molecules by bacterial adhesins depends on whether the receptor is present in the fluid or the surface-immobilized phase. For example, strains of *A. naeslundii* and *S. mutans* bind acidic PRPs such as PRP-1 in acquired pellicle, but do not bind the same PRPs in saliva fluid (Ruhl et al., 2004). Physicochemical studies have shown that the conformation of PRP-1 is altered upon binding to hydroxyapatite (Elangovan et al., 2007). Presumably this conformational change upon adsorption unmasks a bacterial binding domain. Hidden binding domains such as these are termed “cryptitopes.”

The major salivary proteins known to interact with oral bacteria are summarized in Table 1. Although there is undoubtedly some bias in the species that have been chosen for investigation, it is clear that streptococci possess the most diverse range of binding specificities for salivary proteins of all oral bacteria. This is perhaps not surprising because oral streptococci constitute approximately 60%–80% of the total microbial population in early supragingival dental plaque. *Actinomyces* spp., *Haemophilus* spp., and *Veillonella* spp. constitute most of the remainder of cells in plaque within the first 4–8 h after tooth cleaning (Diaz et al., 2006), and these bacteria coaggregate with streptococci or bind a more limited range of salivary components. *P. gingivalis* and *Fusobacterium nucleatum* require anaerobic conditions for growth and are not found at high levels in initial supragingival biofilms. The importance of oral colonization by *H. pylori* has yet to be properly evaluated, but there is concern that the survival of this species in oral biofilms could provide a reservoir for infection of the stomach. There have been several reports of *H. pylori* adhesion to salivary macromolecules and this is still an active area of research (Linden et al., 2008; Prakobphol et al., 2000; Veerman et al., 1997; Walz et al., 2009).

The most abundant enzyme in saliva is α -amylase, and this is the receptor for proteins produced by a number of species of oral streptococci. Surveys of isolated streptococci demonstrated that whereas strains of *S. mitis*, *S. cristatus*, *S. parasanguinis*, and *S. gordonii* bound α -amylase, no *S. sanguinis*, *S. oralis*, or *S. mutans* strains adhered (Douglas et al., 1990; Nikitkova et al., 2013; Scannapieco et al., 1994; Scannapieco et al., 1995). On this basis, α -amylase binding has been suggested as a useful test for discriminating between oral streptococci (Douglas et al., 1990). Adhesion to α -amylase has been most thoroughly studied in *S. gordonii*. This organism produces two amylase-binding proteins, AbpA (20 kDa) and AbpB (82 kDa) (Tanzer et al., 2003). α -Amylase remains active when bound to streptococci, and thus may provide oligosaccharides from dietary starch that could be used by the streptococci or by neighboring bacteria in biofilms (Nikitkova et al., 2013).

Compared with other oral streptococci, *S. mutans* expresses few different polypeptides on its cell surface. Mutans streptococci are not generally found in nascent supragingival plaque, and inhabit areas of the teeth such as cracks and fissures that are protected from fluid and masticatory shear forces. Once established, mutans streptococci are difficult to remove because they are

Table 1 Constituents of saliva that mediate adhesion or aggregation of oral bacteria

Salivary component	Species of bacteria bound	Bacterial adhesin
α -Amylase	<i>S. gordonii</i>	AbpA, AbpB

	<i>P. gingivalis</i>	

^aAntigen I/II proteins of *S. gordonii* are SspA and SspB.

^b*S. mutans* produces one antigen I/II adhesin, designated P1, PAc, antigen I/II or antigen B.

^cAbsent or at low concentration in acquired salivary pellicle.

often embedded in extracellular polysaccharide matrices, derived from the action of glucosyltransferase and fructosyltransferase enzymes on sucrose (Koo et al., 2013). The possibility of preventing adhesion by mutans streptococci is attractive and has been the subject of intensive research efforts. Both *S. mutans* and *S. sobrinus* adhere *in vitro* to pellicles on the surface of hydroxyapatite (Gibbons et al., 1986). However, these species appear to use different mechanisms for attachment because *S. sobrinus*, but not *S. mutans*, requires glucan polymers for adhesion. *S. mutans* is aggregated in the presence of parotid saliva by a high M_r (>300 kDa) protein termed salivary agglutinin (Carlen et al., 1998). An approximately 170 kDa adhesin on the surface of *S. mutans* was found to be critical for adhesion to salivary pellicle and saliva-mediated aggregation, because disruption of the coding gene abrogated adhesion by *S. mutans*. This protein has been variously described as antigen B, PAc, P1, and antigen I/II. The receptor for antigen I/II has now been identified as gp340, a molecule that interacts with surfactant protein D and has a role in innate immunity (Loimaranta et al., 2005; Prakobphol et al., 2000). A specific peptide corresponding to amino acids 1025–1044 of antigen I/II from *S. mutans* is highly effective at blocking binding of *S. mutans* to gp340 and has been suggested as a possible anti-caries treatment agent (Li et al., 2009). One or two copies of antigen I/II protein genes are present in many oral and extra-oral streptococci, including *S. cricetus*, *S. pyogenes*, and *S. gordonii* (Brady et al., 2010). In contrast to *S. mutans*, disruption of antigen I/II genes *sspA* and *sspB* in *S. gordonii* reduces adhesion to gp340 by only ~40% (Jakubovics et al., 2005). Residual binding is because of two families of cell surface adhesin polypeptides, the CshA/CshB proteins that form fibrillar structures and Hsa (GspB in *S. gordonii* M99) sialic acid-binding adhesin.

The sialic acid-binding adhesins of *S. gordonii* mediate binding to mucin MG2 (Takamatsu et al., 2006). However, similar to gp340, MG2 also has bacterial binding properties in the peptide backbone structure. For example, the N-terminal region of MG2 is recognized by *S. mutans* and *A. actinomycetemcomitans* (Ge et al., 2004; Liu et al., 2002). MG2 has not been detected in salivary pellicle, and may be more important for aggregation of bacteria than adhesion to surfaces. Mucin MG1 is found in the acquired pellicle, but is not bound by streptococci. Only *H. pylori* and *Haemophilus* spp. bind to MG1 (Linden et al., 2008; Veerman et al., 1995). *Haemophilus* spp. appear to recognize peptide motifs of MG1 and the large quantities of carbohydrates on MG1 mucin are not involved in binding. In contrast *H. pylori*, a persistent colonizer of the mucin-rich gut environment, expresses several lectin-like adhesins, including SabA, BabA, and AlpA/B, that combine to produce strong adhesion to many glycosylated polypeptides in the oral cavity.

PRPs, including proline-rich glycoprotein (PRG), have diverse bacterial binding properties when immobilized on surfaces. These molecules mediate attachment of antigen I/II-bearing streptococci including *S. mutans* and *S. gordonii* (Ruhl et al., 2004). Antigen I/II protein of *S. mutans* binds PRPs *in vitro* (Russell and Mansson-Rahemtulla, 1989). In addition, lectin-like interactions that are inhibited by carbohydrates have been demonstrated between *S. oralis* or *S. gordonii* and PRG (Murray et al., 1992). *F. nucleatum* and *A. naeslundii* also recognize PRG, and PRG promotes adhesion of these organisms to hydroxyapatite surfaces (Gillece-Castro et al., 1991; Ruhl et al., 2004). A small peptide (RGRPQ) that is released by proteolytic action of *S. gordonii* on PRP-1 inhibits adhesion and promotes desorption of *A. naeslundii* from immobilized PRP-1 (Drobni et al., 2006). Therefore, streptococcal protease activity may be important in competition for binding sites in salivary pellicle.

Like PRPs, statherin interacts with bacteria only when it is immobilized on surfaces. Statherin is unstructured in solution and folds upon adsorption onto hydroxyapatite to form a bacteria-binding motif in the C-terminus (Goobes et al., 2006). Type 1 fimbriae of *Actinomyces* spp. and long fimbriae of *P. gingivalis* recognize and bind to statherin (Amano et al., 1996; Li et al., 2001). Interestingly, these fimbriae also bind PRPs, although at least in the case of *P. gingivalis*, distinct regions of fimbrial proteins are required for interactions with PRPs and statherin (Amano et al., 1996). Surface-bound statherin also promotes adhesion of *F. nucleatum* and *C. albicans*, but retards adherence of *S. mutans* (Johansson et al., 2000; Nakagaki et al., 2010; Shimotoyodome et al., 2006).

Interactions with oral epithelia

As mentioned earlier, the healthy soft oral tissues are heavily populated by microorganisms (Aas et al., 2005). However, cell adherence and invasion are also common virulence factors of many pathogens. In the oral environment, cell adherence provides retention to the soft oral surfaces, without which the pathogen would be washed away by the saliva. Cell invasion can offer an escape mechanism from a hostile host immune system and from antimicrobial therapeutic agents. Therefore, it is not surprising that cell adherence and invasion capabilities are found in oral pathogens.

The periodontopathogen *A. actinomycetemcomitans* is recovered more frequently and in higher numbers from oral mucosal surfaces than from subgingival and supragingival plaque (Muller et al., 2001). This species has been isolated from mucosal surfaces in predentate children (Lamell et al., 2000). In addition, the transfer of *A. actinomycetemcomitans* from oral epithelia to tooth surfaces has been demonstrated in human volunteers, indicating that the oral mucosa is the initial site of colonization and the primary reservoir of *A. actinomycetemcomitans* in the oral cavity (Fine et al., 2010). Aae, a 90-kDa surface-exposed protein that is homologous to an epithelial cell adhesin (Hap) produced by *H. influenzae*, mediates weak binding of *A. actinomycetemcomitans* to buccal epithelial cells (Fine et al., 2005). A second *A. actinomycetemcomitans* adhesin involved in adhesion to buccal epithelial cells is ApiA, a 100-kDa protein also known as Omp100, a member of the *Yersinia* spp. YadA family of autotransporter adhesins (Yue et al., 2007). Combined gene knockout mutations of *apiA* and *aae* completely abrogated the ability of *A. actinomycetemcomitans* to bind human buccal epithelial cells. *A. actinomycetemcomitans* also invades gingival epithelial cells through actin-dependent or actin-independent mechanisms (Brissette and Fives-Taylor, 1999).

P. gingivalis is not only capable of cell adherence and invasion but also of transmission between different cell types (Yilmaz et al., 2006). This intercellular transmission is a likely mechanism for persistence of an inflammatory pathogen in host tissue. Cell invasion of atheromatous tissue has been suggested as a virulence mechanism linking *P. gingivalis* with cardiovascular disease (Olsen and Progulske-Fox, 2015).

At least two fusobacterial adhesins participate in attachment to mammalian cells. The FadA adhesin is a 12-kDa outer membrane protein, and the second adhesin is a galactose inhibitable protein called Fap2 that also mediates adhesion to *P. gingivalis* (Copenhagen-Glazer et al., 2015; Fardini et al., 2011). Host cell adherence of *F. nucleatum*, mediated by Fap2, is also hypothesized to play a role in the involvement of this bacterium in preterm labor (Copenhagen-Glazer et al., 2015). Further, Fap2 is involved in enrichment of *F. nucleatum* at sites of colon adenocarcinoma through adhesion to Gal-GalNAc receptors and protects tumor cells from immune attack by binding to and activating the human inhibitory receptor TIGIT (Abel et al., 2016; Gur et al., 2015). Thus, through the activities of Fap2, *F. nucleatum* may promote the development and/or progression of colon cancer. It is expected that identification of other adhesins involved in cell adherence by major oral pathogens could lead to important therapeutic strategies.

Bacteria–Bacteria Interactions

Coaggregation and coadhesion in spatiotemporal oral biofilm development

All oral bacteria coaggregate with at least one genetically distinct cell type (Kolenbrander and London, 1993). Coaggregation is the phenomenon in which a dense suspension of one cell type, for example *S. oralis*, when mixed with a dense suspension of another cell type, for example *A. naeslundii*, forms clumps or coaggregates and often within seconds these coaggregates settle to the bottom of the suspension (Kolenbrander et al., 2006). Coadhesion is a term often used to describe cell–cell recognition between a suspended cell type and one already attached to a surface. Coaggregation partners are usually from different genera, but some partnerships are intragenetic and intraspecific between strains. These latter two kinds are especially seen among viridans streptococci. This special property may be critical for the development of initial streptococcal communities on freshly cleaned teeth. In addition, most streptococci also bind to receptors in the acquired pellicle and may contribute to their being the most numerous bacteria found in the initial microflora (Nobbs et al., 2011). Their adherence to the surface provides numerous opportunities for other species and genera to bind to them and establish multispecies communities through growth and adherence of additional species, which facilitates the succession of species on tooth surfaces (Fig. 3).

Among the first reported examples of large-scale succession of bacteria was the evidence in the 1960s that progression from periodontally healthy sites to gingivitis was accompanied by a shift from predominately Gram-positive bacteria to predominately Gram-negative bacteria (Theilade et al., 1966). The “experimental gingivitis” model, in which volunteers abstain from oral hygiene for up to 21 days, continues to be used to monitor microbial changes upon transition from health to gingivitis, although the model has been enhanced by the application of more powerful analysis techniques. Such models continue to show enrichment of Gram-negative species in gingivitis such as *Fusobacterium nucleatum* subsp. *polymorphum*, *Lautropia* sp. HOTA94, and *Prevotella oolorum*, whereas certain Gram-positive species such as *Rothia dentocariosa* are associated with health

Metabolic interactions and cell–cell signaling

The development of global profiling technologies such as microarrays and “-omics” techniques has heralded a new era for the study of interbacterial communication and interactions in complex biofilm systems such as those present in the oral cavity. Microarrays and RNASeq allow the measurement of an entire bacterial genome response to a relevant stimulus such as integration of cells into a biofilm or interaction with a different species of bacteria. These methods can be supplemented with the proteomics or metabolomics to investigate global changes in protein or metabolite concentrations, respectively. From these and other studies it has become clear that bacteria respond to contact with cells of other species by changing their patterns of gene expression and hence their phenotypes. Therefore, bacteria in multispecies biofilm communities are physiologically different from isogenic cells, which have been studied in laboratory monocultures. This has profound implications for oral microbiologists because studies exclusively focused on bacteria in isolation cannot be extrapolated to complex dental plaque communities without further empirical evidence. Some of the interactions that occur between bacteria in dental plaque are shown in Fig. 4.

Many species that are commonly found in dental plaque do not grow in axenic laboratory cultures when provided with unmodified saliva as the sole source of nutrients. It is likely that the growth of these species in the oral cavity is enabled by the metabolic activities of nearby bacteria. Beneficial interactions can arise through metabolic cooperation, where the combined action of enzymes from multiple species allows the efficient degradation of a complex substrate, or through nutrient exchange where the waste products of one species are used as a nutrient source for a microorganism with different metabolic requirements. Several studies have shown that microbial consortia are more efficient at degrading substrates found in saliva than single species of bacteria. For example, in chemostat cultures supplied with hog gastric mucin as the major source of carbon and energy, a five-member consortium grew but not efficiently. Introduction of new species with different glycolytic and proteolytic activities led to their stable integration into the community and increased the total yield of bacteria from the substrate (Bradshaw et al., 1994). A microbial consortium isolated from dental plaque consisting of *S. mitis* Biovar 2, *S. gordonii*, *S. cristatus* and *A. naeslundii* was able to degrade purified human mucin MG1, whereas these species in isolation were unable to catabolize this substrate (Wickström et al., 2009a, b). Degradation of mucins is a complex process and appears to be more efficient when mucins are in suspension than when they are bound to a surface (Wickström et al., 2009a, b).

Nutritional interactions influence the growth of periodontal pathogens. For example, mutualistic growth as a consequence of cross-feeding has been demonstrated between *P. gingivalis* and *T. denticola* (Grenier, 1992). Succinate produced by *T. denticola* serves as a nutrient source for *P. gingivalis*, whereas isobutyric acid, a product of *P. gingivalis* metabolism, enhances the growth of *T. denticola*. Oxygen tension is an important factor for periodontal pathogens, because many of these organisms are obligately anaerobic. The presence of aerobic, facultative anaerobic, or oxygen-tolerant species in dental plaque may be sufficient to deplete oxygen to levels that are consistent with growth of obligate anaerobes. Thus, aerobic growth of the strict anaerobe *P. gingivalis* was enabled by the presence of the relatively aerotolerant *F. nucleatum* (Bradshaw et al., 1997).

S. gordonii promotes the recruitment of *P. gingivalis* into biofilms *in vitro* through interactions mediated by the *P. gingivalis* major and minor fimbrial antigens (FimA and Mfa, respectively) (Daep et al., 2011; Simionato et al., 2006; Wright et al., 2013). The close proximity of cells enhances their capacity for metabolic exchange (Kolenbrander et al., 2010). In this pairing, the metabolite 4-aminobenzoate/*para*-amino benzoic acid (*p*ABA) has been shown to be a key nutrient for colonization by *P. gingivalis*. *S. gordonii* produces *p*ABA, a metabolite in the folate biosynthesis pathway, through the chorismate-binding enzyme Cbe. *S. gordonii* mutants lacking the gene encoding Cbe do not support the accumulation of *P. gingivalis* in biofilms. Exogenous *p*ABA results in up-regulation

Fig. 4 Interbacterial interactions in dental plaque. Secreted signaling molecules such as competence-stimulating peptides (CSP) or autoinducer-2 accumulate around all bacterial cells in the multispecies community. The concentration of signaling molecules rises and falls in proportion to the density and diversity of bacterial cells. Various synergistic interactions have been described in oral biofilms. Exchange of metabolites between bacteria enables communities of cells to degrade substrates that cannot be utilized by individual species. Removal of oxygen by aerobic bacteria or facultative anaerobes creates pockets of anoxia that support growth of obligately anaerobic bacteria. The presence of specific receptors and adhesins on different bacteria results in coaggregation. If one partner also possesses adhesins for salivary pellicle receptors, then the coaggregated bacteria will attach to the surface in a process called coadhesion. Antagonistic interactions also occur between oral bacteria. Examples are the production of bacteriocins by *S. mutans*, and production of H₂O₂ by oral viridans streptococci. In addition, acidogenic bacteria create low-pH conditions that inhibit many other microorganisms.

of genes encoding both FimA and Mfa in *P. gingivalis* and hence promotes heterotypic biofilm formation with *S. gordonii*. Interestingly, in a murine infection model pABA enhances the colonization and survival of *P. gingivalis*, but reduces virulence, indicating that this metabolite plays a complex role in regulating microbe-host interactions (Kuboniwa et al., 2017).

The ability to recycle nutrients is important for species growing in the presence of lactic acid-producing oral streptococci. Certain oral bacteria such as *Veillonella* spp. can use lactate as an energy source. In gnotobiotic rats, the presence of *S. mutans*, and in particular strains that produce large amounts of lactic acid, enhances colonization by *Veillonella alcalescens* (McBride and Van der Hoeven, 1981). *In vitro* studies on the relationship between *Veillonella atypica* and *S. gordonii* have revealed a novel signaling pathway by which *V. atypica* cells induce the upregulation of *amyB* gene expression and α -amylase enzyme activity in juxtaposed *S. gordonii* (Egland et al., 2004). This appears to be an active mechanism by which *V. atypica* releases a cue, possibly maltotriose or maltose-containing sugars, which increases the production of lactic acid from intra- or extracellular carbohydrates by *S. gordonii* and thus maximize the benefits from the interaction (Johnson et al., 2009).

Lactic acid is also a key nutrient for *A. actinomycetemcomitans* (Brown and Whiteley, 2007). However, hydrogen peroxide (H_2O_2) produced and excreted by many oral streptococci such as *S. gordonii* is potentially inhibitory to *A. actinomycetemcomitans*. It has been shown that when the *A. actinomycetemcomitans* catalase is overwhelmed and unable to tolerate the H_2O_2 from *S. gordonii*, *A. actinomycetemcomitans* instead uses the glycosidase enzyme Dispersin B to degrade the biofilm matrix in the local area and to move to a safe distance from *S. gordonii* cells (Stacy et al., 2014). In *S. gordonii* and many other oral streptococci, the majority of H_2O_2 produced is derived from the metabolism of pyruvate (Barnard and Stinson, 1996). Interestingly, *Streptococcus cristatus* strains (previously *Streptococcus oligofermentans* (Jensen et al., 2016)) produce H_2O_2 from the oxidation of lactic acid through the action of lactate oxidase, a product of the *lox* gene (Liu et al., 2012). The H_2O_2 produced by the oxidation of lactate inhibits the growth of the lactic acid tolerant species *S. mutans* (Liu et al., 2012; Tong et al., 2007; Tong et al., 2008).

H_2O_2 produced by oral streptococci is an important mediator of interspecies competition, at least *in vitro* (Redanz et al., 2018). As noted above, H_2O_2 is a substrate for salivary lactoperoxidase and it is not known exactly how this enzyme modulates the antimicrobial properties of streptococcal-produced H_2O_2 *in vivo*. Nevertheless, there is a correlation between increased numbers of *S. sanguinis* or other peroxidogenic streptococci in plaque and reduced levels of *S. mutans* or periodontopathogens such as *T. forsythia* or *A. actinomycetemcomitans* (Fakhrudin et al., 2018); Ren et al., 2017; Socransky et al., 1998). Although *S. mutans* strains on the whole do not produce large amounts of H_2O_2 , this species has a different weapon in its armory: bactericidal peptides known as bacteriocins or mutacins (Merritt and Qi, 2012). Several bacteriocins from *S. mutans* have been described and production of these molecules is strain-dependent. Under conditions that support the synthesis of bacteriocins *in vitro*, *S. mutans* can compete effectively with neighboring bacteria including *S. sanguinis* (Kreth et al., 2008). However, it should be noted that both *S. gordonii* and *S. sanguinis* can inhibit bacteriocin production by *S. mutans* and a clear role for bacteriocins *in vivo* is yet to be demonstrated.

Cell-cell communication is a fundamental process governing the structure and organization of biofilm communities. A number of bacterial signaling systems have been described to date, and of these autoinducer-2 (AI-2) and peptide signals appear to be the most important in oral biofilms. AI-2 is the product of the *luxS* gene that is present in a variety of Gram-positive and Gram-negative oral bacteria (Pereira et al., 2013). Many aspects of AI-2 signaling remain to be elucidated. However, it is clear that this signal evokes a broad range of responses in many bacterial species. In *S. mutans*, for example, microarray analysis has revealed that almost one-third of the transcriptome (the total number of distinct mRNA sequences produced by the cell) is affected by AI-2 (Sztajer et al., 2008). AI-2 is required for biofilm formation by *A. actinomycetemcomitans* and is a key determinant of mutualistic biofilm formation by *S. oralis* and *A. naeslundii* (James et al., 2006; Rickard et al., 2006). Neither *A. naeslundii* nor *S. oralis* was able to grow in a glass flowcell in monoculture using saliva as the sole nutrient source. However, these two organisms formed a dual-species biofilm when coinoculated. A *luxS* mutant of *S. oralis* that did not produce AI-2 was unable to grow in monoculture or in coculture. Addition of chemically synthesized AI-2 restored growth in cocultures of *A. naeslundii* and the *S. oralis luxS* mutant, thereby giving AI-2 the status of a bona fide signaling molecule (Rickard et al., 2006).

Signaling with AI-2 is essentially species independent because many species produce and/or respond to the same signal. In contrast, small peptide signals produced by Gram-positive bacteria are species-specific cell density-dependent (quorum sensing) signals. These molecules were first shown to be involved in competence, a physiological state in which bacteria are able to take up DNA. It is now known that competence-stimulating peptides (CSP) of oral streptococci influence a number of physiological processes in addition to competence, including bacteriocin production by *S. mutans* and biofilm formation (Perry et al., 2009; Shanker and Federle, 2017). The combination of competence and bacteriocin production by *S. mutans* enables this organism to obtain DNA from neighboring *S. gordonii* cells in biofilms (Kreth et al., 2005). When the donor *S. gordonii* contained a shuttle plasmid, *S. mutans* cells that acquired DNA were able to maintain the plasmid during subsequent rounds of replication. Analysis of whole-genome sequences can reveal indicators of past events of horizontal gene transfer, the uptake and incorporation of DNA from a heterologous organism into the replicating DNA of a host. Such indicators include characteristic sequence patterns of mobile genetic elements including transposons or lysogenic bacteriophage, or the presence of DNA sequence "islands" containing a different GC content from the rest of the chromosome. Analysis of oral bacterial genome sequences provides strong evidence that "foreign" DNA is present in the genome sequences of many strains including *S. mutans* UA159, *P. gingivalis* W83, and *F. nucleatum* ATCC25586. The potential for DNA transfer between heterologous bacteria in oral biofilms is a concern because this could enhance the spread of antibiotic resistance between bacteria.

Cell-cell sensing may also occur in response to direct contact between cells. It has been demonstrated that *S. gordonii* senses coaggregation with *A. oris* and responds by changing the expression of 23 genes, including 9 genes involved in arginine metabolism

and transport (Jakubovics et al., 2008). It appears that this sensing depends on the action of a secreted *S. gordonii* protease, Challisin, which apparently cleaves proteins from the cell surface of *A. oris*, potentially releasing amino acids or peptides that can be uptaken by *S. gordonii* (Mohammed et al., 2018).

Methods of studying oral biofilms

The study of oral biofilms was first reported by Antonie van Leeuwenhoek, who in 1683 described oral bacteria ("very little living animalcules") sampled from plaque between his own teeth (Bardell, 1983). van Leeuwenhoek's prescient descriptions included coaggregating bacteria, and the fact that bacteria in dental biofilm are more resistant to vinegar treatment than the same bacteria suspended from a dispersed dental biofilm. To date, most knowledge of oral biofilms is based on analysis of the composition of dental biofilms sampled from healthy or diseased sites. Sampling is generally performed using dental instruments, paper points, or obtained from extracted teeth. Plaque samples can then be analyzed microscopically (as first performed by van Leeuwenhoek), by culturing techniques or, as has been performed more recently, by genomic approaches (see earlier text). Interactions between identified cultivable bacteria can be studied *in vitro* under planktonic or biofilm conditions. Biofilms can be grown in static biofilm models (usually wells of a 96-well plate), or under flow conditions such as those created in the disposable flow cell system described in Fig. 5. This model involves inoculating bacteria into a track constructed from a microscope slide, a coverslip, and silicone sealant (Kolenbrander et al., 1999). Medium such as diluted saliva is pumped through the flowcell continuously and the system is maintained at 37°C. If required, the flowcell can be run under anaerobic conditions. Biofilms in the flowcell can be stained non-disruptively and examined under the confocal laser scanning microscope. More recently, microfluidics systems have been used to provide tighter control over the shear forces and to reduce the requirements for large volumes of growth media or saliva (Nance et al., 2013).

An *in situ* approach for studying dental plaque is the retrievable enamel chip model system (Fig. 6). A volunteer wears an acrylic appliance on each side of the mandible. Each appliance contains three $3 \times 3 \times 1$ mm enamel chips, as shown in the figure (Palmer Jr. et al., 2001). Enamel chips are prepared from extracted third molars of humans and sterilized. Thus, six replicates are possible for a time point. However, usually two time points are chosen, for example, 4 and 8 h of wear. The appliance is removed at the proper time and the enamel chips are retrieved, incubated with fluorescently conjugated specific antibodies or oligonucleotide probes, and processed for microscopy without disturbance to spatial relationships within the native biofilm. Use of the retrievable enamel chip model and confocal microscopy has confirmed the presence of coaggregation interactions in the development of initial oral communities (Palmer Jr. et al., 2003). Multispecies communities of streptococci and actinomyces developing *in situ* were shown to be composed of interdigitated mixed species, and not mono-species arranged side by side. Thus, evidence provided by the retrievable enamel chip model confirmed earlier cultivation-based observations that initial colonization is nonrandom and follows the sequential colonization of species. Many different *in situ* devices have been described to model different aspects of biofilm formation, including the accumulation of biofilms in protected regions that mimic the development of dental caries (Prada-Lopez et al., 2016).

Fig. 5 Flowcell model for developing biofilms *in vitro*. Viewed from above (top diagram) and from the side (bottom diagram), the flowcell consists of two parallel tracks with a working volume of 250 μL per track. Each track is connected by tubing to a reservoir on the right and to a pump on the left. Saliva or culture media from the reservoir condition the glass surfaces before inoculation of oral bacterial species, which adhere to the conditioned surfaces. Saliva or media is pumped at about 200 $\mu\text{L min}^{-1}$ to remove unbound cells and then continues to be pumped as a source of nutrient. Adherent cells and development of multispecies communities are monitored using fluorescent dyes to stain the cells and confocal microscopy to view the cells.

Fig. 6 Retrieval enamel chip for modeling dental plaque formation *in vivo* and multispecies bacterial communities on the enamel surface. (a) Two intraoral acrylic appliances are in place in a volunteer's mouth. The mandible carries both appliances, each containing a groove to accommodate, side-by-side, three small enamel chips prepared from sterilized extracted human teeth (each chip, $3 \times 3 \times 1$ mm, arrowheads). At certain times (usually after 4 and 8 h of wear), an appliance is removed and the chips are stained and viewed as described in the legend to Fig. 4. (b) Confocal micrograph of 4-h-old plaque *in vivo* showing initial community composed of two species identified by reaction with fluorescently conjugated anti-*Streptococcus gordonii* DL1 (green; this organism bears a surface-exposed adhesin that recognizes receptor polysaccharides (RPS) on other streptococci) and anti-RPS (red). Only a few cells are stained with the general nucleic acid stain, Syto-59 (blue), indicating the sparse nature of initial colonization of enamel. (c) Confocal micrograph of 8-h-old plaque showing communities composed of at least three species, cells reactive with anti-*S. gordonii* DL1 (green), cells reactive with anti-RPS (red), and antibody-unreactive cells stained with Syto-59 (blue). Panels (b) and (c) show juxtaposition of different cell types forming multispecies communities and not mono-species colonies in developing dental plaque.

Oral Diseases

The microbial inhabitants of the oral cavity generally exist in a harmonious, commensal relationship with the host. Alteration of this relationship often follows a disturbance to the habitat and results in disease. Disturbances that can perturb the composition of the commensal, harmonious oral microflora and lead to dental disease include antibiotic intake, increase in carbohydrate consumption, or physiological changes such as alteration in the composition or flow rate of saliva, hormonal changes, and immunosuppression. The unexpected appearance of microbes at sites not accessible to them under normal conditions following tooth extraction or other trauma might also alter the host-microbe balance and initiate oral disease. The chronic presence of biofilms on tooth surfaces is often sufficient to initiate disease without additional factors.

Plaque-Related Diseases

Dental caries

Dental caries, or tooth decay, is the localized destruction of dental hard tissues by acidic by-products from bacterial fermentation of dietary carbohydrates. Studies on the etiology of dental caries have their roots in the early part of the twentieth century. Toward the end of the nineteenth century, the infectious agents of the major causes of death such as tuberculosis, cholera, and anthrax had been isolated. Identification of these deadly pathogens and the subsequent development of effective countermeasures were enabled by

advances in the formulation of growth media and the development of techniques for isolating and studying bacteria. W.D. Miller applied these techniques to study oral microbes and reported in 1890 that bacteria inhabiting the mouth were able to produce acid from fermentable carbohydrate when incubated at body temperature (Ruby et al., 2010). This work supported studies that had shown that acid was able to dissolve teeth. In the 1940s, R.M. Stephan discovered that following a glucose rinse, bacteria in dental plaque produced a rapid decrease in pH (Bowen, 2013). Return toward the pH baseline was slow. The total extent of exposure to acidic conditions is the primary determinant for whether demineralization of the tooth enamel will occur. However, in natural dental plaque, hydrogen ions are not uniformly distributed and there may be areas of differing pH within single biofilms (Bowen, 2013; Xiao et al., 2012).

Dental caries is associated with changes in the metabolism and composition of the oral microbiota at specific sites. Caries is a preventable chronic disease that progresses slowly in most people and is the primary cause for oral pain and tooth loss. Under acidic conditions, lesion formation occurs by dissolution of the tooth enamel and the transport of calcium and phosphate ions away into the surrounding environment. The initial stages of caries are reversible, and remineralization can occur, particularly in the presence of fluoride (Gao et al., 2016).

Sucrose has a pivotal role in caries etiology as it is the most cariogenic of all sugars (Sheiham, 1987). Molecular biology approaches enabled the identification of genes and metabolic pathways involved in sucrose metabolism by cariogenic bacteria (Bowen et al., 2018; Takahashi, 2015). The three properties that are distinctive characteristics of cariogenic bacteria are as follows: (1) the ability to rapidly import sugars. For this, cariogenic bacteria utilize high- and low-affinity transport systems that continue to operate at low pH (3.95–4.10); (2) acid production. An efficient glycolytic pathway rapidly produces a low pH plaque environment; and (3) aciduricity, particularly the ability to maintain the above activities under highly acidic conditions. Animal models have shown that abolishing any of the three properties impaired the ability of oral streptococci to colonize, persist, or generate caries. In addition, the ability of *S. mutans* to cause caries is associated with the capacity to produce extracellular polysaccharides (glucans and fructans) and intracellular polysaccharides (Busuioc et al., 2009; Koo et al., 2013). Glucans (glucose polymers) and fructans (fructose polymers) are synthesized from sucrose using extracellular glucosyltransferase and fructosyltransferase enzymes, respectively (Bowen et al., 2018). Glucans and fructans play an important role in *S. mutans* adhesion and accumulation on tooth surfaces and in the formation of the extracellular polysaccharide matrix, which is part of the structural integrity of dental biofilms. Glucans and fructans, together with intracellular polysaccharides generated from sucrose, provide an energy source for continued acid production once sources of dietary sugars become exhausted.

Caries-associated bacteria such as mutans streptococci and *Lactobacillus* spp. metabolize sugars to lactic acid. The decrease in surrounding pH inhibits metabolism and growth of many bacteria comprising the normal oral microflora. *S. mutans* is highly tolerant of low pH conditions (Buckley et al., 2014). The strongly acidic conditions facilitate the dominance of *S. mutans* in the bacterial community by restricting competition from neighboring plaque bacteria. This, in turn, increases tooth demineralization in a carbohydrate-dependent manner. *V. parvula*, a Gram-negative oral anaerobe, can potentially reduce the cariogenic potential of *S. mutans* by metabolizing the lactate produced by *S. mutans* to weaker acids, predominantly propionic acid. In addition, cariogenic acids can be neutralized by microbial degradation of arginine into basic end products, namely, urea or ammonia. The major mechanism for the production of ammonia from arginine is the arginine deiminase system, which is present in some oral streptococci such as *S. sanguinis* or *S. gordonii* (Nascimento et al., 2013). Urea produced from arginine or present in saliva secretions can also be catabolized by oral bacteria that express urease enzyme, such as *Actinomyces naeslundii* or *Streptococcus salivarius*, again producing the basic molecule ammonia (Barboza-Silva et al., 2005). High levels of arginolytic (arginine-degrading) and ureolytic (urea-degrading) enzymes in dental plaque correlate with reduced caries experience (Nascimento et al., 2009). The delivery of arginine, or of probiotic bacteria that express high levels of the arginine deiminase system, potentially may be an approach to combat localized acid production in oral biofilms and to control dental caries (Huang et al., 2016; Huang et al., 2018; Nascimento et al., 2013).

Polymicrobial nature of dental caries

In the past, the “specific plaque hypothesis” guided caries research in a search for a specific pathogen or pathogens involved in caries (Rosier et al., 2014). Currently, however, it is generally considered that the microbiology of dental caries is more complex, and that disease arises from an ecological shift from a health-associated community to a more acidogenic, and hence pathogenic, microbial community (Marsh and Zaura, 2017). The transition towards disease is mediated by changes in the local environment such as repeated cycles of low pH following frequent sugar uptake. There are multiple different types of health-associated community, and it is possible that some are more prone to undergoing the transition towards pathogenicity than others (Zaura et al., 2017) (Fig. 7). There are also several different types of cariogenic community, and many different species in addition to *S. mutans* have now been associated with caries including *Scardovia wiggsiae*, *Slackia exigua*, *Bifidobacterium* spp., *Granulicatella elegans* and many others (Fakhruddin et al., 2018). Thus, the elimination of a single species such as *S. mutans*, for example, with a vaccine, may not be completely effective in preventing dental caries in humans as this will simply make more room for one or more of the many acidogens remaining.

In developed and developing nations, the abundance of dental caries is highest in underprivileged groups, largely due to poor oral hygiene and lack of access to dental treatment facilities. In the developing world, malnutrition is an important factor that contributes to dental caries (Psoter et al., 2005). Malnutrition in infants and children leads to poorly calcified enamel that is highly susceptible to decay. In addition, saliva secretion rates and salivary concentrations of calcium, chloride, and protein are reduced in malnourished children.

Fig. 7 Microbiological changes that lead to dental caries. In health, microbial communities in dental plaque can be described as cooccurrence networks. In this depiction, large circles represent the entire community, while smaller circles indicate individual species (OTUs). The size of the smaller circles indicates the relative abundance of the species. Different genera are shown as different colors. In some cases, multiple species of the same genus may be present. Connections between circles represent significant cooccurrence of species. Every individual will possess a unique microbial community that broadly matches one of the predominant cooccurrence networks. Environmental selection for acidogenic species, for example through the frequent and/or extensive intake of sugars, leads to changes in the relative abundance of different species, as well as losses and gains of species in the dental plaque microbial community. Overall, this results in microbial communities that are prone to generating significant quantities of cariogenic acids from carbohydrates (shown by pink shading). There are multiple dysbiotic states, each containing different combinations of acidogenic and aciduric species. It is not yet known whether specific health-associated networks are more prone to undergoing the transition to dysbiosis or whether there are correlations between specific health-associated networks and certain disease-associated networks. In this figure, one health-associated community is able to transition to any of the four dysbiotic states, whereas other communities can only transition to certain states.

The sites most susceptible to dental caries are fissures on the occlusal (biting) surface followed by approximal surfaces (areas between adjacent teeth) where the developing plaque is relatively protected from mechanical clearance by the tongue, salivary wash, and oral hygiene. In industrialized countries, a growing proportion of older adults retain their teeth. Gingival recession associated with old age exposes the susceptible cementum surface of the root to bacterial colonization. Exposed root dentine is especially vulnerable to demineralization by plaque acids because of its relatively low mineral content compared with enamel, and consequently there is a high incidence (approximately 60% of individuals aged 60 and older) of root surface caries in aging individuals. *Actinomyces* spp., in particular *A. naeslundii*, have been associated with root surface caries together with mutans streptococci and lactobacilli (Chalmers et al., 2015; Do et al., 2017; Takahashi and Nyvad, 2016). However, new molecular techniques for bacterial identification are reshaping our view of the organisms associated with dental diseases and have revealed that species such as *Streptococcus mutans*, *Olsenella profusa*, *Prevotella multisaccharivorax*, and *Lactobacillus crispatus* are also associated with root surface caries (Chen et al., 2015).

Periodontal diseases

Periodontal disease (“peri,” around; -odontal from “odous,” tooth) is a general term to describe a collection of bacteria-induced inflammatory conditions ranging from gingivitis, a transient gingival (gum) inflammation, to extensive destruction of the ligaments and of the alveolar bone supporting the teeth. Gingivitis usually initiates with bacterial colonization and the formation of a multi-species biofilm (dental plaque) on the tooth surface adjacent to the gingiva. The biofilm, consisted mostly of anaerobic Gram-negative bacteria and spirochetes, extends along the surface of the tooth roots and initiates irritation of the soft tissue supporting the tooth. Minor gingival inflammation is frequently accompanied by gingival bleeding. This inflammation is reversible. However, if left untreated, periodontitis will follow with the destruction of the collagenous attachment fibers of the periodontal ligament and of the alveolar bone supporting the teeth. Periodontitis is characterized by the loss of periodontal attachment due to the presence of a gap, or pocket formed between the tooth and its supporting tissues. The presence and extent of periodontal pockets (measured in millimetres using a periodontal probe) is the most common method for diagnosing and evaluating periodontitis (Savage et al., 2009).

Fig. 8 Example of bone resorption in periodontitis associated with Down syndrome: radiograph shows loss of bone (indicated by arrows) between incisors of a 22-year old suffering from Down syndrome (*left*) compared with a 29-year-old healthy individual (*right*).

Untreated, periodontitis will lead to resorption of the alveolar bone (Fig. 8) and eventually to tooth loss. The progression of periodontitis is episodic, with active and inactive phases of tissue destruction, which reflects the opposing actions of bacterial challenges and host immune responses.

Periodontal diseases are currently divided into gingivitis (a reversible condition) and periodontitis (American Academy of Periodontology, 2015). Gingivitis is subclassified according to its source or inducing factor, for example, plaque, systemic factors, medications, malnutrition, systemic bacterial and viral diseases, fungal origin, genetic or traumatic. Periodontitis is classified according to the rate of disease progression, as chronic or aggressive. Gingivitis and periodontitis are subclassified by the distribution of lesions (localized or generalized). Periodontal diseases are highly prevalent. Gingivitis affects up to 90% of the worldwide population, whereas severe periodontal disease (pocket depth ≥ 6 mm) affects $\sim 8\%$ of adults aged over 30 years in the United States (Eke et al., 2018).

Although bacteria are essential for the initiation and progression of periodontitis, host factors play a major role in determining disease outcome (Hajishengallis, 2015). Hypo-responsiveness of the host's immunity associated with smoking, diabetes, or HIV infection, or with genetic disorders such as Down syndrome or impaired neutrophil function facilitate bacterial invasion of host tissues (Reynolds, 2014; Stabholz et al., 2010). However, hyper-responsiveness of certain immunological pathways results in a barrage of inflammatory mediators secreted by the host and is considered to be the main contributor for tissue destruction involved in chronic periodontal disease. Lipopolysaccharide extracted from periodontal pathogens such as *F. nucleatum* and *P. gingivalis* causes increased secretion of proinflammatory cytokines such as interleukin- 1β (IL- 1β) and tumor necrosis factor- α (TNF- α), and of the chemokine IL-8 by macrophage-like cells *in vitro* (Huang et al., 2004; Martinho et al., 2016). These immunomodulators are hypothesized to enhance tissue destruction and progression of periodontal diseases. IL-1 genotypes were associated with aggressive periodontitis. IL- 1β , in particular, was associated with susceptibility to periodontitis, because of its ability to induce RANKL (receptor activator for nuclear factor κB ligand) (Belibasakis et al., 2011). RANKL is a cytokine belonging to the TNF family and is essential for the induction of osteoclastogenesis (bone resorption). Osteoblasts (mononucleate cells that are responsible for bone formation) and bone marrow stromal cells produce RANKL, and its signal is transduced by the specific receptor, RANK, which localizes on the cell surface of osteoclast progenitors that differentiate into osteoclasts that promote bone resorption.

In the periodontal pockets, the bacterial biofilm is in close contact with the epithelium. Bacteria-secreted enzymes and toxins break down the gingival lining, and neutrophils are recruited to the infected site and initiate an inflammatory process. Massive neutrophil recruitment and high levels of the proinflammatory cytokines interferon- γ , TNF- α , and IL-1 β were found in the fluids of subcutaneous chambers (a model representing local infection involved in periodontitis) inserted into mice 2 h after challenge with *P. gingivalis* (Burns et al., 2006). Secretion of these proinflammatory cytokines in response to *P. gingivalis* was dependent on functionality of the Toll-like receptor 2 (TLR2) pattern recognition receptor.

Activated neutrophils also convert arachidonic acid to proinflammatory mediators prostaglandin E₂ and leukotriene B₄, which induce quintessential inflammatory symptoms such as heat, redness, swelling, and pain. By secreting proinflammatory cytokines and toxic agents such as oxidants and by phagocytosis of invading bacteria, the neutrophils usually restrain the infection, and inflammation subsides. If the infection persists because of lack of hygiene, leading to an overwhelming challenge to the host, or genetic vulnerability, the neutrophils continue to secrete proinflammatory agents. Recruitment of additional leukocytes including macrophages and lymphocytes accelerates tissue damage leading to a chronic inflammation.

Polymicrobial nature of periodontal disease

Periodontal disease involves complex interactions between the host, subgingival dental plaque and environmental factors such as smoking. As with dental caries, no single species is entirely responsible for periodontal disease, and disease results from a shift in the microbiota, known as dysbiosis, resulting in dental plaque that is enriched in Gram-negative, anaerobic and proteolytic bacteria. At least three species, *T. denticola*, *T. forsythia*, and *P. gingivalis*, have been commonly found together. On the basis of checkerboard DNA-DNA hybridization, a technique that allows the detection of 40 or more different species of bacteria in many samples simultaneously, these three species were found to commonly associate with one another and with periodontal disease (Socransky et al., 1998). These species have been termed the “red complex.” Several studies have investigated the microbiome of periodontal disease using 16S rRNA gene sequencing. For example, in one study the genera *Prevotella*, *Porphyromonas*, *Treponema* and *Fusobacterium* were enriched in deep periodontal pockets, whereas *Streptococcus*, *Actinomyces* and *Veillonella* were more abundant in health (Ge et al., 2013). Twenty-one “operational taxonomic units” (OTUs; essentially equivalent to species), including *T. forsythia*, *P. gingivalis* and *Filifactor alocis*, were found to be associated with periodontitis in a study of 30 periodontitis patients and 30 controls. Using checkerboard hybridization, eight taxa including *T. forsythia*, *Parvimonas micra* and *F. alocis* were elevated in saliva samples of periodontitis patients compared with controls (Belstrom et al., 2014).

Sequencing of the 16S rRNA gene has also been used to follow changes in the oral microbiome during the onset of gingivitis (Kistler et al., 2013). In this case, taxa associated with gingivitis onset included *Fusobacterium nucleatum* subsp. *polymorphum*, *Lachnospiraceae* [G-2] sp. HOT100, *Lautropia* sp. HOTA94, and *Prevotella oulorum*, whereas *Rothia dentocariosa* was associated with periodontal health.

Periodontitis initiates from infection by an oral biofilm composed of a diverse bacterial community. It has been suggested that certain species such as *P. gingivalis* may act as keystone pathogens to trigger disease (Hajishengallis et al., 2012). According to the “polymicrobial synergy and dysbiosis” model, these keystone pathogens are present in low numbers, but are critical for disease development (Hajishengallis and Lamont, 2012). They interact with existing colonizers to establish in the biofilm, and subsequently increase the virulence of the whole biofilm by disrupting immune surveillance of the host. Environmental factors such as smoking may render the host more susceptible to attack through modifying the microbial cells or the host immune response.

It is clear that many different combinations of species may be present in periodontally pathogenic biofilms. It is possible that these biofilms share common functions such as metabolic pathways, even if they differ in species composition. Metatranscriptomics has been employed to assess changes in gene expression during the transition from health to gingivitis (Nowicki et al., 2018). Pyrimidine, propanoate and butyrate metabolism were associated with gingivitis, while a range of pathways including carbon fixation in prokaryotes, the pentose phosphate pathway, and pyruvate metabolism, as well as porphyrin and chlorophyll metabolic gene products were associated with health. Genes associated with destructive pathways such as proteolysis and nucleolysis were upregulated in disease, which may reflect the ability of subgingival dental plaque to degrade the host tissue matrix. More studies of this kind on different stages of periodontitis may shed light on the key metabolites that are produced by the combined activities of the microorganisms in the biofilm and trigger host immune responses.

Candidiasis

Oral fungus infections are often called “diseases of the diseased” and some host predisposition usually occurs before the fungus can take hold. Likewise, cures for fungal infections necessitate alleviating the predisposing condition. *Candida albicans* is the most common fungus isolate from oral infections. In approximately half of the population, *C. albicans* is a part of the resident oral microflora and it is most commonly found on the tongue (Mun et al., 2016). Changes in the ecosystem, for example immunosuppression, utilization of broad-spectrum antibiotics, or trauma, lead to overgrowth resulting in infection (candidiasis). Oral *C. albicans* infections are generally associated with an increase in the mycelial (hyphal) form as opposed to the blastospore (yeast) form of the fungus. The virulence factors of *C. albicans* include adhesins that enable adhesion to epithelial cells and to acrylic used in dentures, and secreted proteinases and phospholipase that facilitate invasion of host tissues. A key factor in invasion of host tissues is a peptide toxin termed Candidalysin that is secreted into invasion pockets produced by hyphae, and accumulates to concentrations that cause lysis of host cells (Moyes et al., 2016). Oral candidiasis may appear in a number of chronic and acute forms. Treatment of oral candidiasis involves alleviating the predisposing condition and prescribing antifungal agents.

Extra-Oral Diseases

Oral bacteria are associated with a number of conditions that occur at body sites outside the oral cavity. Chronic inflammation associated with periodontal disease may have adverse consequences for general health. Bacteria can enter the bloodstream during dental surgery or, more frequently, during everyday activities such as toothbrushing or chewing food. These transient bacteremias are usually cleared quickly with no adverse effects. However, on occasion, this may be a route of inoculation for bacterial infections at distal sites. Bacteria in oral biofilms are also of concern for individuals with impaired lung function who require artificial ventilation. Lung infections are a common complication in this group of patients and oral bacteria have been implicated as a source of the infective agents.

Periodontitis-related conditions

Periodontitis and heart disease

Atherosclerosis involves elevated circulating lipids and arterial vessel lipid accumulation, combined with an ongoing inflammatory response. Atherosclerosis initiates by accumulation of excess low-density lipoprotein (LDL) on artery walls. The LDL goes through chemical modifications (lipid oxidation) that stimulate an inflammatory cascade in the intima (interior wall of the artery). Endothelial cells react with the modified LDL by displaying adhesion molecules that capture circulating monocytes and T cells, and by secreting chemokines that traffic the captured cells into the intima. Monocytes proliferate in the intima and mature into macrophages that, together with the recruited T cells, secrete proinflammatory cytokines. The macrophages display scavenger receptors and phagocytose the modified LDL. The intracellular lipid accumulation causes the macrophages to appear foamy under the microscope (foam cells). A yellow “fatty streak” (mix of foam and T cells) atherosclerotic lesion becomes visible. Inflammation continues to drive the growth of the atherosclerotic plaque and leads to the plaque becoming covered by a fibrous matrix formed by migrated smooth muscle cells. Inflammation is also hypothesized to make this cap vulnerable to rupture. Rupture will lead to the development of a blood clot over the break that will cause further narrowing of the blood vessel.

Local or distant (“echo effect”) infections have been proposed to contribute to the inflammatory process in atherosclerosis by accelerating them or by enhancing the inflammatory properties of LDL (Hayashi et al., 2010). Although not conclusive, epidemiological studies support a link between periodontitis and atherosclerosis (Pinho et al., 2013; Tonetti and Van Dyke, 2013). In animal models, *P. gingivalis*, the oral pathogen most associated with chronic periodontitis, is capable of accelerating atheroma deposition (Fukasawa et al., 2012). Atherosclerosis acceleration, as well as periodontitis, in atherosclerosis-prone apolipoprotein E (ApoE)^{-/-} mice was dependent on *P. gingivalis* fimbriae (Gibson 3rd et al., 2004). ApoE^{-/-} mice challenged with a fimbria-deficient *P. gingivalis* mutant did not develop either periodontal disease or accelerated atherosclerosis. Further evidence that oral bacteria are involved in atherosclerosis has been provided by studies on human samples. *P. gingivalis* and *A. actinomycetemcomitans* were detected in human atherosclerotic plaque by molecular bacterial identification techniques (Kozarov et al., 2006).

Periodontitis and diabetes

It has been noted that diabetics have increased risk of periodontal diseases (Casanova et al., 2014; Holmstrup et al., 2017; Sanz et al., 2018). Human cell culture and animal studies support the concept that diabetes leads to increased inflammatory activity in the periodontal pocket (Polak and Shapira, 2018). Conversely, there is some evidence that treatment of periodontal disease has a positive effect on glycemic control of diabetes; possibly involving effects on insulin resistance (low responsiveness of cells to uptake blood sugar in response to insulin, and the hallmark of type 2 diabetes). There is evidence that inflammatory periodontal diseases increase insulin resistance (Martinez-Herrera et al., 2017). Overexpression of TNF- α in periodontal lesions has been hypothesized to promote insulin resistance, thereby exacerbating problems with glycemic control. Further research is needed to clarify this aspect of the relationship between periodontal diseases and diabetes.

Adverse pregnancy outcomes

Conflicting epidemiological data have been reported regarding the role that periodontal disease plays as a risk factor for preterm labor and low birth weight (Sanz and Kornman, 2013). Controversy also exists about the benefits of treating periodontitis during pregnancy. Cultivable and noncultivable species of putative periodontal pathogens have been detected in intrauterine infections that induced or were involved in preterm labor. Oral bacteria such as *F. nucleatum*, *P. gingivalis*, *F. alocis* and *Campylobacter rectus* have been isolated (often as pure cultures) from amniotic fluid, placenta, and chorioamniotic membranes of women delivering prematurely (Cobb et al., 2017). A possible mechanism linking *F. nucleatum* with preterm deliveries was supported by using a murine model, where *F. nucleatum* intravenously injected into pregnant mice and thus simulating transient bacteremia caused by periodontal infection, resulted in preterm deliveries (Han et al., 2004; Stockham et al., 2015). Fetal death was due to local infection of the fetoplacental unit rather than systemic effects of maternal bloodstream infection. The sequence of infection paralleled that in humans. The *F. nucleatum* infection initiated in the deciduas basalis of the placenta. This site is characterized by large venous sinuses where blood flow rate is slow and the shear force is low, which provides an opportunity for *F. nucleatum* to adhere and invade the endothelial cells. It was suggested that attachment to, followed by invasion of host cells is an important virulence mechanism for *F. nucleatum* infections of the placenta. A key adhesin involved in attachment and invasion was later identified as the *F. nucleatum* galactose-inhibitable adhesin Fap2 (Copenhagen-Glazer et al., 2015). As the fetal death rate was significantly reduced in TLR4-deficient mice, a TLR4-mediated inflammation rather than the bacteria *per se*, was suggested as the cause of fetal loss (Liu et al., 2007). A synthetic TLR4 antagonist significantly reduced fusobacteria-induced

fetal death and may represent a promising approach of using anti-inflammatory agents for future treatment or prevention of bacteria-induced preterm births.

Infective endocarditis

Infective endocarditis (IE) is a rare but serious inflammation of the heart valves that is usually caused by bacteria. Despite advances in disease prediction, diagnosis, and treatment, mortality for this condition remains high at approximately 20% (Dunne et al., 2014). Oral streptococci along with *S. aureus* and *Staphylococcus epidermidis* are consistently identified as the most common causative agents of IE (Que and Moreillon, 2011). Less frequent isolates from IE lesions include Gram-negative organisms such as *A. actinomycetemcomitans* and *P. gingivalis* (van Winkelhoff and Slots, 1999). Culture-independent methods such as metagenomics have also detected oral bacteria in infective endocarditis lesions (Cheng et al., 2018). The process of IE involves translocation of bacteria to the site of infection, attachment to the endothelial lining, and bacterial growth. The ability of bacteria to bind platelets has also been suggested as a virulence mechanism because endocardial vegetations consist of bacterial cells encased in a fibrin matrix containing platelets and host proteins (Kerrigan et al., 2007). Virulence factors for IE include bacterial adhesins (e.g., EmaA of *A. actinomycetemcomitans*) (Tang et al., 2008), exopolysaccharides (glucans and fructans of *S. mutans*) (Taniguchi et al., 2010), and serine rich repeat proteins (GspB/Hsa) of *S. gordonii* and other oral streptococci (Bensing et al., 2018). A screen for IE virulence factors of *S. sanguinis* using signature-tagged mutagenesis identified several housekeeping genes involved in synthesis of the cell wall, amino acids, and nucleic acids (Paik et al., 2005; Turner et al., 2009).

Patients with preexisting heart conditions are at significantly increased risk of IE, and there is ongoing debate as to whether these individuals should receive antimicrobial prophylaxis in the form of antibiotics or chlorhexidine mouthrinse during dental treatment (Diz Dios, 2014). However, as there is a lack of compelling evidence that antimicrobial prophylaxis is effective in reducing the incidence of IE, and in light of concerns that overuse of antibiotics leads to resistance mechanisms in bacteria, the latest (2007) guidelines of the American Heart Association recommend antimicrobial prophylaxis during dental treatment for only a very small number of patients (Wilson et al., 2008).

Ventilation-associated pneumonia

Pneumonia affects between 9% and 27% of patients in US hospitals that rely on mechanical assistance for ventilation (Kalanuria et al., 2014). The etiology of ventilator-associated pneumonia (VAP) is complex, and may involve a number of opportunistic pathogens such as *S. aureus*, *Streptococcus pneumoniae*, *Pseudomonas aeruginosa* and *H. influenzae*. There is a growing body of evidence that the oral cavity is a route of entry for VAP pathogens. Using culture-independent techniques, respiratory pathogens *S. aureus* and *P. aeruginosa* were shown to invade dental plaque of approximately one third of patients following intubation and were present concurrently in both the lower respiratory tract and dental plaque of a number of VAP patients (Sands et al., 2017).

Strategies for Disease Control

Diagnosis of Dental Caries and Periodontitis

Visual and radiographic diagnoses of caries are in common use and are usually adequate. However, objective diagnostic tests with predictive value for the risk assessment of caries are greatly desired. The occurrence of mutans streptococci and lactobacilli in plaque correlates with their levels in saliva. On the basis of this correlation, commercial chair-side tests for semi-quantification of these indicator organisms in saliva samples have been introduced. These tests utilize user-friendly selective culture media for determining levels of mutans streptococci and lactobacilli in saliva and have exhibited some value in infants, toddlers, and in elderly subjects (Tanabe et al., 2006). However, since *S. mutans* and *Lactobacillus* spp. are not always strongly increased in caries, the sensitivity of this test for detecting all cases of caries will be limited. Including methods to detect other species such as *Scardovia wiggsiae* may improve the situation (Eriksson et al., 2017). Ultimately, longitudinal studies are necessary to determine the true value of these tests in predicting caries.

At present, microbiological sampling is not routinely used for diagnosing gingivitis or periodontitis. Gingivitis is identified by signs of gingival inflammation and by a bleeding response to a periodontal probe. Periodontitis is diagnosed when attachment loss (pockets of >3 mm) is found in addition to symptoms of gingivitis. Loss of alveolar bone associated with periodontitis can be detected using X-rays. Molecular methods for characterization of disease-associated microflora may one day be harnessed to develop more sophisticated techniques for diagnostic and prognostic evaluation of periodontal disease. However, the complexity of the microbial shifts in periodontitis make it unlikely that individual microbial biomarkers will ever be useful alone. Instead, it will be necessary to develop panels of markers that reflect multiple different disease states. Attempts have already been made using next-generation sequencing of the microbiome and machine learning to identify the 10 best biomarkers to use in combination (Szafranski et al., 2015).

Prevention and Control of Oral Microbial Diseases

Dental caries

The development of dental caries relies greatly on the frequency of sugar intake. If sugars are consumed continuously throughout the day, the pH stays below a critical level for extended times, and the tooth surfaces cannot regain lost mineral content

(remineralize). Therefore, control of sugar and particularly sucrose intake is a simple measure for controlling dental caries. In addition, regular mechanical removal of plaque by toothbrushing controls the number of bacteria in biofilms on teeth and limits the capacity for acid production from sucrose. Arginine also has potential to reduce caries since it is metabolized by dental plaque bacteria into alkali, thus preventing the acidification of dental plaque (Geraldini et al., 2017). In addition, arginine appears to destabilize dental plaque, potentially reducing the overall microbial burden (Kolderman et al., 2015). Pit and fissure sealing in children and adolescents is also effective in lowering the bacterial burden at caries-susceptible sites, and this is an important preventative strategy for controlling dental caries (Ahovuo-Saloranta et al., 2017).

In the early twentieth century, Frederick S. McKay observed that people living in particular areas had mottled, stained teeth due to an ingredient of their domestic water supply. He also noticed that mottled teeth showed absence of decay. In 1931 this water ingredient was found to be fluoride (McKay, 1953). Fluoride, administered in drinking water, toothpaste, or topically by a professional, acts as a catalyst for the diffusion of calcium and phosphate into the tooth and remineralization of the crystalline structures in the lesion (Robinson, 2009). In addition, calcium fluorapatite is less soluble than calcium hydroxyapatite, and thus incorporation of fluoride makes the enamel more resistant to demineralization. Fluoride also has direct adverse effects on the microorganisms in dental plaque. By increasing membrane permeability to protons, fluoride effectively reduces acid tolerance of bacteria, including *S. mutans*. However, strains of *S. mutans* with resistance to fluoride have been isolated and it is possible that resistance will be selected in the population through the widespread use of fluoride, negating the beneficial effects of fluoride against cariogenic bacteria (Liao et al., 2017).

Periodontal disease

In otherwise healthy individuals, periodontal diseases are generally preventable by applying good daily oral hygiene. However, once periodontitis takes hold it is not possible to eliminate the disease. The common approach to halt progression of periodontal disease is mechanical plaque removal, known as debridement (Drisko, 2014). Smoothing, or debridement, the tooth root is often performed to facilitate daily hygiene by the patient, enhance healing, and retard plaque re-accumulation. Antibiotics may be administered systemically or locally via a sustained releasing device to control infection. Bone grafting followed by tooth transplant can be performed if extensive alveolar bone loss occurred resulting in tooth loss (Matarasso et al., 2015).

Innovative studies by Serhan and Van Dyke elucidated the proinflammatory importance of the neutrophil-derived leukotriene B_4 and prostaglandin E_2 . While searching for endogenous anti-inflammatory compounds, they discovered lipoxins that derive from arachidonic acid, and resolvins and protectins that derive from omega-3 fatty acids (Serhan et al., 2008). These compounds rapidly halt and resolve inflammation. Preliminary results demonstrated that rabbits receiving topical application of lipoxins and resolvins were protected against periodontitis, compared to the placebo group, which developed severe periodontitis. Furthermore, transgenic rabbits expressing high levels of lipoxin in their blood were resistant to periodontitis-induced atherosclerosis, whereas wild-type rabbits developed periodontitis and atherosclerosis following oral infection with *P. gingivalis*. Lipoxins and resolvins can regenerate bone and show great potential for treating periodontal diseases in humans (Van Dyke et al., 2015). It is anticipated that advances in our understanding of microbial interactions in health- or disease-associated dental plaque will provide a basis for fundamental improvements to future dental care procedures.

Summary

Oral Microbiology is characterized by complexity. Biofilms on oral surfaces contain tens or hundreds of different species, all interacting with one another and contributing to the overall function of the system. The biofilm interacts with host tissues and with environmental factors such as dietary intake or inhalation of smoke. Oral biofilms are present in health, and evidence now indicates that species are relatively well-conserved between individuals, at least in comparison with other “microbiomes” on the body. Nevertheless, we each contain our own oral microbiota, and it is possible that some combinations of microorganisms are more prone to developing disease than others. Understanding the transition from health to disease is critical for the rational design of new strategies to enhance oral health. A great deal more work is needed before we can fully understand how and why oral disease occurs.

Glossary

Eukaryotic organisms Organisms having one or more cells, with well-defined membrane-bound nuclei.

Filamentous fungi Fungi that grow as long, multicellular strands.

Genetic engineering Technique used to modify genetic information of microorganisms, reprogramming for a desired purpose (e.g., to produce a substance it would not naturally produce).

Global transcription machinery engineering Approach for reprogramming gene transcription to elicit cellular phenotypes important for technological applications.

Metabolic engineering Improvement of cellular activities by manipulation of enzymatic, transport, and regulatory functions of the cell with the use of recombinant DNA technology.

Metabolomics Metabolite profiling, measuring the real outcome of the potential changes suggested by genomics or proteomics. It investigates regulation and metabolic fluxes in individual microorganisms.

Molar yield Gram dry weight of cells or product per mole of substrate (e.g., carbon source) utilized.

Oxidative TCA cycle The tricarboxylic acid (TCA) cycle, also known as the Krebs cycle or the citric acid cycle, is the major pathway for the complete oxidation of acetyl-CoA to CO₂ (catabolism) and the generation of energy in the form of ATP. Reactions of the TCA cycle also function in metabolic processes (anabolism) other than energy generation.

Primary metabolites Metabolites produced during and required for growth of the microorganism.

Prokaryotes Bacteria and blue green algae (cyanobacteria) with nuclear material not limited by membrane and DNA not organized in chromosomes.

Reductive TCA cycle Biochemical pathway including the carboxylation of pyruvic acid to oxaloacetic acid, which can be further converted to L-malic acid, fumaric acid, and/or succinic acid, dependent on the organism in use. The reactions are in the reverse direction of the oxidative TCA cycle and no energy is generated.

Submerged fermentation Production of different substances by growing producer microorganisms in depth in liquid culture.

Systems biology Systematic study of interactions in the organism using modeling, global analysis (or omics analysis), mapping of interactions between cellular components, and quantification of dynamic responses in living cells resulting in the quantitative description of the biological system under study.

Abbreviations

ARA	Arachidonic acid
DHA	Docosahexaenoic acid
EFA	Essential fatty acids
ESA	L-Trans-2,3-epoxysuccinic acid
GLA	γ-Lineolenic acid
GRAS	Generally recognized as safe
2-KGA	2-Keto-D-gluconic acid
5-KGA	5-Keto-D-gluconic acid
PHA	Polyhydroxyalkonate
PHB	3-Hydroxybutyric acid
PUFA	Polyunsaturated fatty acids
SCFA	Short chain fatty acids
SCO	Single-cell oil
TCA	Tricarboxylic acid

[☆]Change History: July 2016. Israel Goldberg and J. Stefan Rokem updated the article.

This article is an update of I. Goldberg, J.S. Rokem, Organic and Fatty Acid Production, Microbial, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 421–442.

Defining Statement

Organic acids are used as food acidulants and building blocks for other useful chemicals. Fatty acids were recently recognized for their beneficial health properties and a prospective energy source. The potential of various microorganisms to synthesize various organic and fatty acids will be highlighted with emphasis on the existing industrial large-scale production processes. The information has been updated and now includes data from public sources until June 2016.

Introduction

Organic and fatty acids are broadly distributed in nature and were used by humans in their natural forms since early ages. Presently, organic acids are used mostly as food acidulants and as building blocks for other useful chemicals of low and high molecular weight (polymers). Although high concentrations of acids are produced by various microorganisms, microbiological production process is important for only a few acids and an economic alternative to chemical synthesis. Within the world's fermentation market, organic and fatty acids constitute a significant portion, especially with the production of citric acid, L-lactic acid, acetic acid, gluconic acid, and itaconic acid (Table 1). Recent developments in the biotechnology field, environmental pressures, increased recognition of the positive contribution of specific fatty acids to health and prevention of chronic disease, steady increase in price of petrochemicals, integration of fermentation and agricultural products (e.g., corn), consumer awareness for natural instead of chemical food constituents (i.e., the use of natural L-malic acid in foods instead of the chemically produced DL-malic acid), and recent requirements for a specific isomer of the acid for biodegradable and natural polymer production (i.e., L- or D-lactic acid) may result in much improved economics for the implementation of the biological route for the industrial production of organic acids (Table 1).

This article describes the potential of various microorganisms to synthesize high amounts of organic and fatty acids. It emphasizes those acids that are produced in the industry by large-scale fermentation processes.

Organic Acids

Organic acids are intermediates or end products of cellular metabolism. Accumulation of various organic acids is the basis for a varied and extensive industry, often based on biological production methods. The majority of the organic acids discussed in this article are produced and excreted to the medium at high concentrations by filamentous fungi such as *Aspergillus* sp. (citric, L-malic, gluconic, itaconic, L-trans-2,3-epoxysuccinic, gallic, and kojic acid) and *Rhizopus* sp. (fumaric, L-lactic, and gallic acid). Most of these acids are intermediate metabolites in the primary biosynthetic metabolism and, therefore, do not accumulate under normal growth conditions (primary metabolites). Stress appears to be a common requirement for the unusually high production and accumulation of these acids, since under stress conditions most of the carbon source is used for acids production (metabolite) rather than increase

Table 1 Production of selected organic acids by chemical and biological routes^a

Acid	Annual production (t)	Chemical process	Biological process	Year
Food acids				
Citric acid	1,600,000	—	+	2007
Acetic acid	10,000,000	+	+	2005
Lactic acid	240,000	—	+	2006
D-Gluconic	87,000 ^b	—	+	2004
L-Tartaric	35,000	—	+	2003
Malic acid	60,000	+	+	2006
Ascorbic acid	110,000	+	(+)	2001
Fumaric acid	90,000	+	—	2008
Gallic acid	8,000	+	—	2010
Building blocks				
Polyhydroxyalkonates	50,000	—	+	2006
Itaconic	80,000	—	+	2009
Succinic acid	15,000	+	+	2003
Acrylic	4,200,000	+	—	2016
Adipic	2,760,000	+	—	2004
Propionic acid	176,000 ^c	—	+	2003

^aThe estimated annual world production of the various acids is based on information in the published literature. The order of the acids is based on the volume produced by biological routes.

^bThe worldwide consumption of D-gluconic acid based on major industrial applications.

^cEstimated consumption in the United States.

in biomass production (growth). Other acids (2-ketogluconic, 5-ketogluconic, acrylic, and adipic acid) are produced by bacteria under aerobic conditions, while succinic acid is produced by bacteria under anaerobic conditions. The formation of the latter acid is usually the way by which these bacteria regenerate NAD from the accumulated NADH, and thus the accumulation of succinic acid strictly parallels and is required for growth.

Food Acids

Citric Acid

Citric acid (2-hydroxy-1,2,3 propanetricarboxylic acid, $C_6H_8O_7$) (Fig. 1) is a white or colorless, odorless, crystalline solid. It is highly soluble in water, freely soluble in ethanol, and slightly soluble in ether. Citric acid has three carboxyl groups and, therefore, is a good buffer for pH control.

The discovery of citric acid has been credited to the eighth century alchemist Jabir Ibn Hayyan. The acid was first isolated in pure form in 1784 by Carl Wilhelm Scheele, who crystallized it from lemon juice.

Citric acid is found in almost all plants and in many microorganisms and animal tissues and fluids. It is a key element in the physiological oxidation of fats, proteins, and carbohydrates to carbon dioxide and water.

Citric acid, with very low toxicity, is mainly used as a flavoring agent and preservative in food and beverages, bestowing tartness to fruit and soft drinks. Citrate salts of different metals are used to deliver these metals, in a biologically available form, in food supplements. Citric acid is used in household cleaning chemicals and pharmaceuticals, for storage of blood, in tablets and ointments, and also in cosmetic preparations. It acts as a bacterial inhabitant and as an antioxidant.

The biosynthesis of citric acid has been well studied; however, all the reactions that lead to citric acid are still not fully understood. Citric acid is a primary metabolite formed in the tricarboxylic acid (TCA) cycle, discovered in 1937 by Hans Adolf Krebs (Fig. 2). It has been known for a long time that there is a condensation of a C_4 moiety with a C_2 moiety, both metabolites of pyruvic acid, to form the C_6 molecule of citric acid. In high-glucose media the high yields obtained for citric acid are explained by two different reactions occurring with pyruvic acid. One of the two pyruvic acid molecules (C_3), formed by the glycolytic pathway from glucose (C_6), is converted to acetyl CoA (C_2). The other molecule is carboxylated by a reaction catalyzed by pyruvate carboxylase, which is a part of the reductive direction of the TCA cycle and found to occur in the cytosol in *Aspergillus niger* (Fig. 3). The product of this reaction is oxaloacetic acid (C_4). This acid is first reduced to malic acid (C_4), and enters the mitochondria via a malate–citrate transporter, converted to malic acid, which together with acetyl CoA will form the citric acid. The enzyme performing this reaction, citrate synthase, is only present in the mitochondria.

The current world production of citric acid is estimated to be 1.6 million tonnes per year (Table 1), whereof 99% is produced by microbial fermentation. Several microbial species are able to accumulate citric acid during primary metabolism; both fungi, such as *A. niger*, *Aspergillus wentii*, *Penicillium luteum*, and *Trichoderma viride*, yeast like *Candida guilliermondii*, and *Saccharomycopsis lipolytica*, and bacteria such as *Arthrobacter paraffineus* and *Corynebacterium* sp. For production, *A. niger* is used (Fig. 4).

Modern fermentation technologies yield 95 kg of citric acid from 100 kg of sugar supplied, with final concentrations of over 200 g L^{-1} . The modifications that have led to the high producing industrial strains are well-kept secrets; however, mutant isolations by academic laboratories include high sugar tolerance and growth and acid production at low pH. This is an example where fermentation of sugar(s) is converted to an end product (citric acid) at very high efficiency. The medium for optimal production of citric acid should contain a sugar concentration of between 120 and 250 g L^{-1} , a nitrogen source (ammonium salts) over 2 g L^{-1} , a phosphate concentration between 0.2 and 1.0 g L^{-1} , $Mn < 10^{-8}$ mol L^{-1} , $Zn < 10^{-6}$ mol L^{-1} and $Fe < 10^{-4}$ mol L^{-1} . The dissolved oxygen concentration should be > 150 mbar, and the pH is 1.6–2.2.

As can be seen for other acids of the TCA cycle (fumaric and L-malic acid, see below), the high molar yield values obtained by the different filamentous fungi are due to the presence of a compartmentalized (in this case cytosolic) activity of a carboxylation enzymatic reaction, resulting in the fixation of carbon dioxide by the unique pyruvate carboxylase (in most eukaryotic cells located in the mitochondria) (Fig. 3).

Two methods are used by industry to manufacture citric acid, the submerged fermentation process (Fig. 5) and the surface method. Small amounts are made by solid-state fermentations, mainly in East Asia. The main industrial organism in use today is *A. niger*. Before the 1973 oil crises, use of yeast grown on *n*-alkanes under submerged conditions was also in use. The yeast most in use was *Yarrowia lipolytica* grown on straight chain paraffins (see also “Isocitric acid”).

The surface method is still in use, being less labor- and energy-intensive and with much lower susceptibility to trace metal ions. The fermentation is carried out in aluminum trays, where spores are dispersed on the surface of the nutrient medium. The fungus forms a mat and yields reported are between 0.7 and 0.9 g g^{-1} of sugar after 1–2 weeks.

Fig. 1 Citric acid.

Fig. 2 The tricarboxylic acid (TCA) cycle (also Krebs cycle and citric acid cycle). With permission from Dr. Paltel, R., Humboldt State University, CA, USA.

The submerged fermentation has higher efficiency and is easier to automate. The carbon source, usually from renewable resources, needs to be analyzed for trace metals, and if present, these should be removed, to avoid inhibition of citric acid accumulation. Both aerated towers, where the air enters at the bottom of the vessel, and stirred-tank fermentors are in use by industry. The required growth mode is the formation of pellets made of the fungal mycelium, with a diameter of 0.2–0.5 mm, that sediment swiftly at harvest. The low pH of the process is critical for obtaining a high yield of citric acid and to avoid the potential accumulation of oxalic acid. The initial inoculum for vegetative growth is, in most cases, spores that require a pH above 5.0 in order to germinate. For production, the pH should be <2 , which also reduces the risk for contamination.

The purification of citric acid from the fermentation broth starts with filtration with the help of filter aids to obtain good separation of the citric acid containing broth and the mycelium (Fig. 5). To avoid oxalic acid in the final product, lime (calcium hydroxide) is added at low pH and calcium oxalate precipitates and is separated from the liquid. Citric acid is then precipitated by increasing lime concentration and raising the temperature to 70–90°C and the pH to 7.2, followed by collection of calcium citrate using rotating filters. To obtain higher purity of citric acid, sulfuric acid is added, reprecipitating calcium sulfate. The citric acid is further treated with activated carbon, cation exchangers, and anion exchangers and finally crystallized either as citric acid or as citric acid monohydrate. The use of solvent extraction (aliphatic alcohols and ketones, amines and phosphines with hydrocarbons are mainly used) for citric acid purification has been introduced more recently and is also used by industry.

The recent sequencing of an *A. niger* strain has shed more light on the potential biochemical mechanisms involved in acid accumulation; however, it should be noted that the sequenced strain is not known to be a major producer of citric acid. Genes coding for several of the enzymes involved in the crucial formation of oxaloacetic acid were found. The identification of the various activities comprising citric acid metabolism and the implicated transporter genes provides the basis for a more complete understanding of the efficient accumulation of citric acid by *A. niger*.

In 2011 the global production reached 1.75 million tons per year and with an estimated increase of ~5% per year. There is an interest to use agro-industrial wastes as a source for carbon, instead of the more expensive sugars that have been the traditional carbon source in large-scale fermentations. There is also renewed interest in using the yeast *Y. lipolytica* for industrial manufacture mainly due to the wider substrate range since in addition to sugars, it can utilize alkanes, plant oils, starch hydrolysates and glycerol. There are no indications in the public domain that this yeast is used now in industry.

Fig. 3 The reductive reactions of the TCA cycle. The abbreviations of the enzymes are ACO, aconitase; CIT, citrate synthase; FUM, fumarase; FRD, fumarate reductase; IDH, isocitrate dehydrogenase; KGD- α , ketoglutarate dehydrogenase; MDH, malate dehydrogenase; PDH, pyruvate dehydrogenase; PYC, pyruvate carboxylase.

The biosynthesis of citric acid is still not completely understood. There are several control points from the entry of the sugar, its metabolism and transport outside of the cells that have been described. Among others it has been proposed that citrate accumulation is dependent on the activity of the NADP specific isocitrate dehydrogenase which was shown using mutants of isocitrate dehydrogenase in industrial strains of *A. niger*. The obligatory high concentration of metabolizable sugar necessary to obtain high titers of citric acid is probably due to the accumulation of fructose 2,6 biphosphate with a stimulating effect on glycolysis with concomitant inhibition of α ketoglutarate dehydrogenase, an enzyme further on in the oxidative TCA cycle. The limited activity of

Fig. 5 Manufacturing of citric acid by a submerged process. Reproduced from Meers, J.L., Milsom, P.E., 1987. Organic acids and amino acids. In: Bu'lock, J., Kristiansen, B. (Eds.), Basic Biotechnology, first ed. London: Academic Press, pp. 359–383, with permission from Elsevier.

isocitrate dehydrogenase (by Mn^{2+} limitation) is another significant factor to achieve augmented citrate accumulation. Another important control point is the inhibition by high citrate of the enzyme phosphofructokinase which is reversed by the accumulation of high concentrations of ammonia, by degradation of intracellular nitrogenous macromolecules. Even though the conditions required for citrate accumulation are well documented, it is still not possible to assign the primary effect of a certain condition.

Gluconic Acid

Gluconic acid (2,3,4,5,6-pentahydroxy caproic acid, $C_6H_{12}O_7$) (Fig. 6) is a noncorrosive, nontoxic, mild organic acid with a brown clear appearance. It is very soluble in water and has a mild and refreshing taste. It is a good chelator at high pH, with better activity than commonly used chelators.

Gluconic acid was discovered in 1870 by Hlasiwetz and Habermann, when glucose was oxidized with chlorine. In 1922 it was isolated from a strain of *A. niger*. Later, other filamentous fungi, such as *Penicillium*, *Scopulariopsis*, *Gonatobotrys*, and *Gliocladium*, and also oxidative bacteria, such as strains of *Pseudomonas*, *Gluconobacter* (*Acetobacter*), *Moraxella*, *Micrococcus*, *Enterobacter*, and *Zymomonas* were found to produce gluconic acid. Already in the 1940s it was possible to obtain good yields of gluconic acid using *A. niger* by fermentation, neutralizing the accumulating acid with calcium carbonate.

The physiological functions of gluconic acid accumulation for these organisms are not clear; one possibility is its contribution to the competitiveness of the organism, removing glucose from the close environment. In the case of *P. expansum* (a phytopathogenic fungus), it was demonstrated that secreted gluconic acid contributed to the colonization and disease development of apple tissues by this fungus.

Gluconic acid is used in the manufacture of metal, leather, and food. It has been accredited with the capability of inhibiting bitterness in foods. Sodium gluconate is permitted in food and it has GRAS (generally recognized as safe) status. This salt is also utilized as a sequestering agent in many detergents, and added to cement to improve the hardening process.

The formation of gluconic acid is different from most other organic acids, since it is formed outside the cytoplasmic membrane, by the enzyme glucose oxidase. This enzyme has been shown to be localized in the cell wall, at least for fungi known to accumulate

Fig. 6 Gluconic acid.

gluconic acid. Glucose in the medium is oxidized in a two-step reaction to gluconic acid; first glucose oxidase oxidizes β -D-glucopyranose to D-glucono-1,5 lactone with the formation of hydrogen peroxide, acted upon by catalase to form water and oxygen (Fig. 7). The hydrolysis of the lactone is spontaneous in aqueous solutions, but occurs six times faster with the enzyme gluconolactonase, resulting in gluconic acid (Fig. 7).

The main route of gluconic acid production has been by fermentation, mainly using *A. niger* in submerged fermentations. The two most important parameters of the fermentation is a high concentration of dissolved oxygen, used directly in the biosynthesis, and keeping pH 4.5–6.5, traditionally achieved by addition of calcium carbonate as the neutralizing agent. Best results are obtained with a high-glucose concentration (110–250 g L⁻¹), low concentrations of nitrogen and phosphorus (<20 mmol L⁻¹), and low concentrations of metal ions. Fermentations with almost quantitative yield (>90% on a molar basis) are completed in less than 24 h. The fact that the oxidation reactions occur outside of the cells allows for reuse of the mycelium up to 14 times. In the current industrial method, neutralization with NaOH allows for the use of higher initial sugar concentrations (up to 350 g L⁻¹) and the pH is then maintained close to 6.5. Recently, enzymatic processes have been introduced by conversion of glucose syrups with less formation of by-products and resulting in fewer problems in the downstream process.

There are alternative ways of gluconic acid production by chemical, electrochemical, and bioelectrochemical routes, but with lower yields than the fermentation processes. Bacteria, mainly *Gluconobacter oxydans*, are reported to be used by industry. Recently, a process based on *Acetobacter methanolicus* was developed. The process utilizes methanol as the carbon source for growth, with the addition of glucose for its conversion to gluconic acid.

It is still considered problematic to produce gluconic acid in an ecofriendly and cost-effective manner, mainly due to the multiple steps involved in the downstream processing, membrane methods are predicted to be optimal for purification. Very high yields of gluconic acid (1.05 g g⁻¹) with glucose solutions of 330 g L⁻¹ have been obtained with dispersed growth of the fungus *A. niger* instead of the conventional pellets widely used in industrial production. The productivity is also increased since the fermentation time with dispersed growth is shortened.

L(+)-Tartaric Acid

L(+)-Tartaric acid (L-2R,3R-dihydrobutanedioic acid, C₄H₆O₆) (Fig. 8) derives its name from the medieval, alchemical term tartarus. It is a white, crystalline powder, odorless, and with an acidic taste. It is a strong organic acid, widely distributed in nature, and classified as a fruit acid (it is the most expensive fruit acid). The acid has two stereogenic atoms and it exists in three stereoisomeric forms – L(+), D(–), and the DL-racemic tartaric acid, which is distinct from the *meso*-tartaric acid. Although the dextrorotatory D(–)-isomer is the 'unnatural' form of the acid, its occurrence in small amounts in nature has been demonstrated. L-tartaric acid is present

Fig. 7 Biosynthesis of gluconic acid. Reproduced from Ramachandran, S., Fontanille, P., Pandey, A., Larroche, C., 2006. Gluconic acid: Properties, applications and microbial production. Food Technology and Biotechnology 44, 185–195.

Fig. 8 L-Tartaric acid.

in its free form or combined with potassium, calcium, and magnesium. It is highly soluble in water, methanol, ethanol, and glycerol but is insoluble in chloroform.

Although tartaric acid was first isolated by the alchemist Jabir Ibn Hayyan, Carl Wilhelm Scheele is credited for its discovery in 1769.

L-Tartaric acid is present in the juices of various fruits, particularly in tamarinds, unripe grapes, and is one of the main acids in wine.

L-Tartaric acid is an extremely versatile acid and it is utilized in a wide range of industries. The largest single application for tartaric acid is as a raw material for the manufacturing of emulsifiers used for bread improvement. An important salt of tartaric acid, potassium hydrogen tartrate (or cream of tartar), has applications as an acidulant for baking powder and sugar confectionery. Tartaric acid is used in the food industry (in particular, in jams, fruit juices, pickles, soft drinks, etc.), in the production of various construction materials, and in certain medicines as an inert bulk substance, since it is not metabolized by the human body. The potassium sodium salt, called Rochelle salt, was the first compound used as a piezoelectric crystal. The acid is a useful raw material for the synthesis of other chiral molecules (e.g., L(+)-, D(-)-tartaric acids are used as chiral auxiliary reagents in the oxidation of alkenes to enantiomerically pure epoxides).

Tartaric acid can be produced by natural and synthetic routes. The natural route involves the recovery of the reddish precipitated salt, potassium bitartrate, from argol, the sediment in wine vats. The synthetic chemical route involves the production of the racemic mixture of tartaric acid from maleic anhydride.

Since the availability of L(+)-tartaric acid from wine is dependent on the climate, and because the chemical process results in the racemic mixture of the acid, attempts have been made to explore alternative biological ways of producing the high-cost tartaric acid. Several patents and reports suggest that various bacteria (such as *Corynebacterium* sp., *Rhodococcus* sp., *Alcaligenes levotartaricus*, *Acinetobacter tartaricus*, and *Pseudomonas agrobacterium*) show a high enzymatic activity of the stereo-specific *cis*-epoxysuccinic acid hydrolase to form L(+)-tartaric acid. Industrial processes based on these organisms are not known.

Currently, the industrial production of L(+) tartaric acid is mediated by transformation of *cis*-epoxysuccinic acid using various organisms that contain high activities of the enzyme *cis*-epoxysuccinate hydrolase (EC 3.3.2.3). The enzyme is convenient to use since it does not require cofactors, metals and is relatively stable. Until now there are no reports of a direct fermentation using sugars as substrates for the production of L(+) tartaric acid and it is still isolated from vinasses, the wastes of wine production or chemically produced.

Malic Acid

Malic acid (2-hydroxybutanedioic acid, $C_4H_6O_5$) (Fig. 9) is a white, odorless, crystalline solid. In contrast to other fruit acids, it is very hygroscopic and has a tendency to lump. Malic acid is a dicarboxylic acid and has an asymmetric carbon and occurs as L(the natural)- and D-isomers.

Malic acid was first described by Sheele who, in 1785, isolated this acid from unripe apples. The name malic is from the Latin for apple, malum.

Malic acid is found in other fruits such as grapes, watermelons, cherries, and in vegetables such as carrots and broccoli. This acid is mainly used in food applications including candy and beverages. It gives a tart taste, lowers the pH, has antimicrobial effects, and confers special blending and flavor-fixing properties. There are also nonfood applications such as use for metal cleaning and finishing, textile finishing, electroless plating, pharmaceuticals, infusions, and paints.

The biosynthesis of L-malic acid from carbohydrates (glucose) is similar to citric and fumaric acid, where the carboxylation of pyruvic acid leads to oxaloacetic acid that is reduced to L-malic acid (Fig. 3). The carboxylation reaction that leads to L-malic acid accumulation allows for a high acid molar yield (based on the glucose utilized).

World production of malic acid is estimated at around 60 000 t per year (Table 1), most of this is made by chemical hydration of maleic or fumaric acid, using high temperature (180–220°C) and high pressure (14–18 bar), yielding the racemic mixture of DL-malic acid.

Biological processes result in the L-isomer of the acid. In one process, species of *Brevibacterium flavum* or *B. ammoniagenes* with high fumarase (fumarate hydratase) activity are immobilized, in either polyacrylamide or κ -carrageenan, and are used to convert fumarate to L-malate. In another efficient process, the yeast *Saccharomyces cerevisiae* was amplified for the enzyme fumarase by cloning the single homologous nuclear gene downstream of a strong promoter. The overproducing strain can be used as free cells or can be immobilized (e.g., in agarose beads or microspheres); it converted fumarate to L-malate at a maximal rate of $65 \text{ mmol L}^{-1} \text{ g}^{-1} \text{ h}^{-1}$, with a yield of approximately 85%.

Fig. 9 L-Malic acid.

After optimization of the fermentation conditions, filamentous fungi, such as *Aspergillus flavus* using glucose, accumulate over 110 g L^{-1} of L-malate. Other species (e.g., *Aspergillus oryzae* and *A. niger*) have also been found to accumulate L-malic acid from glucose. Since these latter fungi are GRAS organisms, these are suitable for food applications.

The use of fermentation for the production of L-malic acid on an industrial scale has not been realized yet, even though non-aflatoxigenic strains, such as *Aspergillus oryzae* are able to produce 154 g L^{-1} with a productivity of $0.94 \text{ g L}^{-1} \text{ h}^{-1}$. The utilization of non-conventional substrates is becoming crucial using low cost substrates instead of expensive sugars. One such substrate, which due to the high volume production of biodiesel, is glycerol. The fungus *Ustilago* is capable of growing as single cells when in its haploid form, lowering the energy demand to agitate filamentous organisms (*Aspergillus*). Concentrations reaching 200 g L^{-1} have been reported. Attempts to use synthetic metabolic engineering for accumulation of L-malic acid is still in its infancy and the yields are much below (molar yield of 60% from glucose) than those reported for whole cell fermentations (140% which is 69% of theoretical yield).

L-Ascorbic Acid (Vitamin C)

L-Ascorbic acid (3-keto-L-gulofuranolactone, vitamin C, $\text{C}_6\text{H}_8\text{O}_6$) (Fig. 10) is a colorless crystal, white or very pale yellow crystalline powder. It is sensitive and will decompose at prolonged exposure to light and air. Vitamin C is an essential nutrient for higher primates and its deficiency will cause scurvy, probably due to the stimulation, by vitamin C, of the oxidation enzymes (oxidases) involved in the formation of collagen. The gene encoding L-gulonolactone oxidase is absent in these animals, and therefore an external source of vitamin C is necessary. L-Ascorbic acid is a strong antioxidant and it protects toward oxidative stress and has been implicated to protect tissues and hinder cardiovascular disease and cancer.

In 1928, Albert Szent Györgi discovered vitamin C (the third vitamin found, and given the third letter in the alphabet) and solved a long debate over the active ingredient with antiscorbutic activity. The name ascorbic acid is derived from a scorbuticus meaning against scurvy. Vitamin C was the first vitamin to be artificially synthesized in 1935.

L-Ascorbic acid is found in citrus fruits such as lemon, lime, and orange and also in vegetables such as cabbage and processed cabbage (sauerkraut). Long before the isolation of L-ascorbic acid, it was known that including lemons and oranges in the diet prevented scurvy.

L-Ascorbic acid is used on a large scale ($110,000 \text{ t}$ in 2001, see Table 1) as an antioxidant in food, animal feed, beverages, pharmaceutical formulations, and cosmetic applications.

The manufacture of L-ascorbic acid is by the Reichstein–Grüssner synthetic pathway introduced in 1934 (Fig. 11). It is a chemical process with one step carried out by biocatalysis; conversion of D-sorbitol to L-sorbose by the bacterium *Gluconobacter suboxydans* (or by the formerly used *Acetobacter xylinum*). The yield of ascorbic acid from the starting material glucose is estimated to be around 50%. The process is energy consuming with high temperatures and pressures necessary for some steps of the process. Economic factors have given rise to tremendous interest for use of alternative processes.

There are several alternatives based on biological processes with 2-keto-L-gulonic acid (2-KLG) as the key intermediate. Potential use of the genera *Gluconobacter* (*Acetobacter*), *Ketogulonicigenium*, *Pseudomonas*, *Erwinia*, and *Corynebacterium* has been looked into furthermore. In the so-called two-stage process, the chemical reactions of the Reichstein–Grüssner process to produce di-acetone-ketogulonic acid are replaced by a second fermentation step, which results in the formation of 2-KLG (Fig. 12).

Another biological route, the ‘one organism route’, has great potential to become commercialized. Here glucose is converted to 2-KLG in one-step fermentation process, using *Erwinia* sp. (able to convert glucose efficiently to 2,5-diketo-D-gluconic acid) engineered with a gene encoding 2,5diketo-D-gluconic acid reductase from *Corynebacterium glutamicum*, resulting in more than 120 g L^{-1} of 2-KLG formed in 120 h of fermentation (Fig. 13). Although biotechnological processes are being exploited for the production of ascorbic acid and Reichstein–Grüssner intermediates, the future goal should be the total replacement of the chemical route by efficient biocatalytic systems for production, using cost-saving starting materials.

The formation by fermentation of 2-KLG is considered well established and with high efficiency using D-sorbitol as substrate, but the ascorbic acid is still not the final product. This fermentation is considered a bio catalytic functionalization of a specific substrate. The choice of carbon source is therefore limited to those with suitable stereochemistry. The two-step fermentation process is well established in China from the 1980s producing around 80% of the world market demand. The challenge, that has still not been resolved, which should result in commercial concentrations of vitamin C, is to convert an appropriate substrate directly to ascorbic acid. The biological conversion of the substrate to 2-KLG must followed by an effective bioconversion to ascorbic acid. One of the attempts has been to use the well-researched conventional yeast, *S. cerevisiae* with its well-developed resources for genetic engineering where three genes, GDP-D-mannose-3,5-epimerase, GDP-L-galactose-phosphorylase and

Fig. 10 L-Ascorbic acid.

Production of 2-keto-L-gulonate, an intermediate in L-ascorbate synthesis, by a genetically modified *Erwinia herbicola*. Science 230, 144–149, with permission from AAAS.

Fig. 12 Alternative processes for L-ascorbic acid production. Reproduced from Bremus, C., Herrman, U., Bringer-Meyer, S., Sahm, H., 2006. L-Ascorbic acid production. Journal of Biotechnology 124, 196–205, with permission from Elsevier.

L-galactose-1-phosphatase from plants should allow for the direct biological formation of L-ascorbic acid. However, the acid accumulates intracellularly at low concentrations. More research on precursor supply, possible compartmentalization and flux analysis to determine the rate limiting step(s) is to reach commercial production with the yeast. *Ketogulonicigenium vulgare* (formerly *Gluconobacter oxydans*) is used in industry to effectively provide the precursor 2-KLG at a concentration of 130 g L^{-1} from 150 g L^{-1} of sorbitol in 72 h.

Fumaric Acid

Fumaric acid (2-butenedioic acid *trans*, $C_4H_4O_4$) (Fig. 14) derives its name from the fact that the acid is found in plants that belong to the genus *Fumaria*, a common European herb. Fumaric acid is the *trans*-isomer of symmetric, unsaturated dicarboxylic acid; the *cis*-isomer is maleic acid. It is produced as a colorless, crystalline powder with a fruit-like taste (a fruit acid), and it is a weak acid which forms diesters, has low solubility in water, and it undergoes additions across the double bond.

Fumaric and maleic acids were discovered in 1817 by Braconnet and independently by Vauquelin during dry distillation of malic acid.

Fumaric acid is widely used in the food industry as an acidulant because it is nontoxic and is the least expensive of the food-grade acids. Fumaric acid solubility in water is low (0.6 g per 100 g at 25°C), and, therefore, in order to increase its application in various foods a cold water-soluble (CWS) fumaric acid, which contains a wetting agent, for example 0.3% w/w dioctyl sodium sulfosuccinate, is used. Fumaric acid is used for the industrial preparation of L-malic acid catalyzed by the enzyme fumarase (see 'Malic acid') and L-aspartic acid, a component of aspartame, by the enzyme aspartase. Other industrial uses of fumaric acid are in jet printing inks, plastics surface coating and paper sizing, and as an intermediate in the preparation of unsaturated polyester and alkyd resins. Fumaric acid is used by the pharmaceutical industry to produce alexipharmic sodium dimercaptosuccinate and ferrous fumarate, as an optical bleaching agent, in formulations for alternative medicine or as fumaric acid esters monoethylfumarate and dimethylfumarate to treat psoriasis.

Fumaric acid does not accumulate under normal growth conditions of microorganisms and its synthesis is carried out through succinic acid by the mitochondrial oxidative TCA cycle (Fig. 2). Various species of the filamentous fungus *Rhizopus* (such as *Rhizopus nigricans* and *Rhizopus oryzae*) produce high concentrations of this acid, which is excreted to the medium. In *Rhizopus*, most of the fumaric acid is formed from pyruvic acid via a carboxylation reaction, yielding oxaloacetic acid, which is converted directly to L-malic acid and then to fumaric acid. These reactions, which are catalyzed by pyruvate carboxylase, malate dehydrogenase, and fumarase, respectively, are localized in the cytosol and are part of the reductive TCA cycle (Fig. 3), carried out under aerobic conditions. The production of fumaric acid from glucose through the reductive reactions of the TCA cycle does not provide net energy and is balanced for carbon, oxygen, and hydrogen. Therefore, part of the pyruvic acid must be utilized through the oxidative TCA cycle to provide energy, mainly for maintenance requirements. It should be noted that, in general, pyruvate carboxylase in eukaryotic organisms is localized in mitochondria, while in certain acid producing filamentous fungi (e.g., *Rhizopus* and *Aspergillus*), the enzyme is situated exclusively in the cytosol and in some cases in both compartments. The cytosolic localization of this enzyme appears to be important for the ability of these organisms to accumulate high concentrations of organic acids.

In the 1940s, fumaric acid was made by fermentation on a commercial scale (about 4000 t per year) using a strain of the fungus *Rhizopus arrhizus* (later named *R. oryzae*). It was the first submerged fermentation process with molds and served as a model for implementing and scaling up the techniques used for submerged fermentations. The biological production of fumaric acid was terminated when the chemical synthesis became economically more attractive. Fumaric acid is a symmetrical molecule having no isomers and, therefore, the biological process offers no specific advantage over the chemical process. Fumaric acid is presently

Fig. 14 Fumaric acid.

produced by a chemical process through the isomerization of maleic acid (or maleic anhydride), obtained from a catalytic vapor-phase oxidation of benzene or C₄ hydrocarbons.

The accumulation and excretion of fumaric acid from glucose by *R. oryzae* (about 100 g L⁻¹ of fumaric acid) occurs under aerobic conditions in a high-glucose (an initial concentration of 120 g L⁻¹) medium containing a limited amount of nitrogen and a neutralizing agent (CaCO₃). Fumaric acid (molar yield of approximately 100%; moles acid produced per mole of glucose utilized × 100), L-malic acid (15 mol%), and succinic acid (5 mol%) are the major acids formed during fermentation. C₄ acid (fumaric, L-malic, and succinic acid) molar yields of 120–145% are obtained after 4–5 days. The high fumaric acid molar yield and C₄ acid molar yield confirm that these acids are produced via a carboxylation reaction of pyruvic acid.

A low cost biological process for fumaric acid manufacture is still a challenge, partly due to the costs of downstream processing, with no low pH processes that are effective. Partly because of inherent technical problems involved in growing filamentous fungi on a large scale. Morphology is the main issue, where pellet growth is desired but not always attainable. Another main cost factor is the price of the substrate estimated to be 40–60% of the total and therefore unconventional C-sources have been and are tested, such as woodchips, dairy manure, crude glycerol (by-product of biodiesel formation) and corn straw and other lignocellulosic sources. Attempts of metabolic engineering has yet not resulted in either productivities or acid concentrations that can compete with the industrial chemical process still in use. Platform organisms, such as *S. cerevisiae* and *Escherichia coli* are being intensively studied to replace the filamentous and potentially pathogenic *Rhizopus* sp. The U.S. Government's Occupational Safety and Health Administration [OSHA] classifies *Rhizopus* species as an allergen and irritant and a cause of hypersensitivity pneumonitis and dermatitis. The concentrations accomplished are orders of magnitudes lower acid (5.6 g L⁻¹, 28.2 g L⁻² respectively compared to 126 g L⁻¹ for *Rhizopus*).

Isocitric Acid

Isocitric acid ((1R,2S)-1-hydroxypropane-1,2,3-tricarboxylate, C₆H₈O₇) (Fig. 15) is a TCA intermediate and an isomer of citric acid. It exists in four isomers and is a chiral molecule, and thus has two enantiomers of each of the isomers.

Isocitric acid (the (–)-D-threo-isomer) is synthesized by all cells as it is an intermediate of the TCA cycle (Fig. 2). Isocitric acid is synthesized from citric acid via the intermediate *cis*-aconitic acid by the enzyme aconitase (aconitate hydratase). Isocitric acid is a minor organic acid found in most fruit juices, especially in blackberries, youngberries, and boyberries, and in vegetables, especially in carrot. The determination of D-isocitric acid has become of importance in the analysis of fruit juices for the detection of illegal additives (adulteration). Since the quantities of citric (see "Citric acid") and isocitric acids are correlated in fruit juices, a too high ratio of citric to isocitric acid indicates the addition of citric acid.

Isocitric acid is mostly used in the food industry (food additive) as a food acidulant, and because of being a chiral molecule, isocitric acid is used in the pharmaceutical industry and as a potential raw material for synthesis of expensive chemicals.

Racemic isocitric acid was first prepared by Fittig and Miller in 1889 by the condensation of chloral with sodium succinate in the presence of acetic anhydride and by the subsequent hydrolysis of the resulting trichloromethylparaconic acid to isocitric acid; this is isolated as the lactone.

Formation of citric and isocitric acid by yeasts using various carbon sources has been the focus of investigations for the past four decades. Most of the research was directed for production of citric acid while isocitric acid was considered as an undesirable by-product. *Y. lipolytica*, several *Candida* species (such as *Candida oleophila*, *Candida parapsilosis*, *Candida brumptii*, *C. guilliermondii*, *Candida zeylanoides*, *Candida pulcherrima*, and *Candida chalmersi*), *Pichia polymorpha*, and *Hansenula pelliculosa* are examples of yeasts that are capable of producing different citric acid/isocitric acid ratios and quantities using various carbon sources, such as hexadecane, tetradecane, glucose, *n*-paraffins, calcium acetate, calcium butyrate, soybean oil, fish oil, canola oil, ethanol, and glycerol. Fermentation conditions, type of carbon source, and the organism utilized determine the amount of isocitric acid formed. It was reported that with *Y. lipolytica* grown on canola oil, up to about 75 g L⁻¹ of isocitric acid and 110 g L⁻¹ of citric acid were produced. It can be expected that an increase in isocitric acid synthesis, on the expense of citric acid, can be obtained in a mutant of *Y. lipolytica* having an amplified activity of aconitase. This strain could then be used more economically than the wild-type strain, for the commercial production of isocitric acid.

The complete genome sequence of *Y. lipolytica* has been determined and is opening up the potential for use of this yeast to produce specific acids (i.e., isocitric) at high productivity.

Fig. 15 Isocitric acid.

There is still a lot of interest to improve isocitric acid accumulation with as low as possible concentration of citric acid (the acid sells for a much higher price than the other acids reviewed). The purification of isocitric acid from the mixture is prohibitively expensive, and marketed isocitric acid is from *Sedum spectabile* (renamed *Hylotelephium spectabile*). The optimization of cultivation conditions and manipulations of the concentrations of iron (co-factor of aconitate hydratase) and itaconic acid (inhibitor of isocitrate lyase) allowed for better ratios of the two acids in the yeast *Y. lipolytica*. The addition of itaconic acid has resulted in a dramatic change in the ratio of isocitric to citric acid to 6:1 in a mutant of *Y. lipolytica*.

Building Blocks

Polyhydroxyalkonates

Polyhydroxyalkonates (PHA) is a large group of polymers based on linear polyesters of 3, 4, 5 and 6-hydroxyacids (Fig. 16).

The molecular weight of PHA can be up to 2 million Daltons. All the monomers are enantiomerically pure and in the R-configuration. The PHA exhibit thermoplastic and elastomeric properties and are easily degraded to carbon dioxide and water. They are considered as good replacements for petroleum-derived polymers, in terms of physical-chemical characteristics and biodegradability.

In 1923, Lemoigne found that spore-forming bacilli make 3-hydroxybutyric acid. In 1927, after using chloroform extraction, he showed that a *Bacillus* sp. accumulated the polymer, which consists of the monomer of 3-hydroxybutyric acid (PHB), where PHB is a specific case of PHA. There are a multitude of possible monomers, of either 3–5 carbon atoms designed as short chain-length PHA or 6–14 carbon atoms, called medium chain-length PHA. A wide variety of bacteria, both Gram negative and Gram positive, have the capability to synthesize PHA. Among these are species of *Pseudomonas*, *Bacillus*, *Ralstonia*, *Aeromonas*, *Rhodobacter*, and even certain *Archaea*, such as *Haloferax sulfurifontis*. The main species in use by industry was initially designated as *Alcaligenes* sp., and today it is called *Cupriavidus* sp. The PHA function as energy storage compounds for the bacteria and are found as discrete cytoplasmic inclusions in the cells.

In the early 1970s, polyhydroxybutyrate was manufactured by the use of *Alcaligenes* sp., accumulating up to 70% of cell dry weight as polymer. However, this process had its problems such as that the product showed brittleness and poor mechanical characteristics. A copolymer of 3-hydroxybutyrate and 3-hydroxyvalerate, BIOPOL, was developed and is used for medical devices such as bioengineered hearts, surgical sutures, meshes, and orthopedic fixtures. Another copolymer of 3-hydroxybutyrate and 3-hydroxyhexanoate is used in the production of nonwovens, binders, flexible packaging, synthetic paper, and medical devices. A recombinant *E. coli*, able to produce a mixture of 3-hydroxybutyrate and 3-hydroxyoctanoate to 90% of its cell dry weight in 24 h, has been developed.

The biosynthesis of PHA consists of three enzymes, PHA synthase, β kethothiolase, and β reductase, which are all found in producing microorganisms. Supply of monomers and polymerization are the two main steps in biosynthesis, and PHA formed is dependent on the carbon source used as well as on the different pathways (three) that are present in different microorganisms; pathway I where the carbon source (sugar) is the precursor, through the formation of acetyl-coA, pathway II where fatty acid degradation delivers the precursors, and pathway III where the polymer is formed through the route of fatty acid biosynthesis.

Attempts to produce PHAs on an industrial scale was initiated in the 1970s by Imperial Chemical Industries using the 1.5 million liter continuous fermentor initially used for production of single-cell protein. The two natural producers, *Ralstonia eutropha* and *Alcaligenes latus* are not ideal for large-scale production since they grow slowly and depolymerize the accumulated PHA and use it as a second energy source. The PHA biosynthetic pathway has been transferred to bacteria with robust central metabolic pathways and capable of using inexpensive carbon sources, engineered *E. coli* produced 80 g L⁻¹ of polyhydroxybutyrate with a productivity of 2 g L⁻¹ h⁻¹. One of the major producers is Telles, a joint venture between Archer Daniel Midlands and Metabolix Inc. producing a corn syrup-based PHA resin, Mirel, reported to have a production capacity of 50,000 t per year.

Itaconic Acid

Itaconic acid (methylenesuccinic acid, C₅H₆O₄) (Fig. 17) is a white colorless crystalline, hygroscopic powder soluble in water, ethanol, and acetone. It is an unsaturated diprotic acid, which derives its unique chemical properties from the conjugation of one of its two carboxylic acid groups with its methylene group.

Fig. 16 General structure of polyhydroxyalkonates. Reproduced from Philip, S., Keshavarz, T., Roy, I., 2007. Polyhydroxyalkanoates: Biodegradable polymers with a range of applications. *Journal of Chemical Technology and Biotechnology* 82, 233–247, with permission from Society of Chemical Industry, granted by John Wiley & Sons Ltd on behalf of SCI.

Fig. 17 Itaconic acid.

Itaconic acid was discovered by Baup in 1837 as a product of pyrolytic distillation of citric acid. The name itaconic was devised as an anagram of aconitic.

Itaconic acid is formed in fermentation of some sugars. In 1929, Kinoshita first showed the acid to be a metabolic product of *Aspergillus itaconicus*. A derivative of itaconic acid (*trans*-phenylitaconic acid) was isolated from another natural source (*Artemisia argyi*).

The biosynthetic pathway of itaconic acid from glucose is similar to that of citric acid, which occurs via the glycolytic pathway and anaplerotic formation of oxaloacetate by CO₂ fixation and via the TCA cycle (Fig. 2). Itaconic acid is formed by the cytosolic enzyme aconitate decarboxylase from *cis*-aconitic acid. Another biosynthetic pathway from pyruvate through citramalic acid, citraconic acid, and itartaric acid also results in itaconic acid (Fig. 18).

In contrast to several other organic acids (e.g., citric, isocitric, lactic, fumaric, and L-malic acid) itaconic acid is used exclusively in nonfood applications, especially in the polymer industry. Itaconic acid derivatives are used in medicine, cosmetics, lubricants, thickeners, and herbicides (e.g., substituted itaconic acid anilides).

Itaconic acid is produced solely by batch submerged fungal fermentation. *Aspergillus terreus* has been used from the 1940s in the fermentation process, which is similar to that of citric acid (see "Citric acid"), that is, it requires an excess of readily metabolizable sugar (glucose syrup, crude starch hydrolysates, and decationized molasses – up to 200 g L⁻¹ sugar), continuous aeration, a low initial pH (between 3 and 5), sufficient nitrogen, high magnesium sulfate concentration (0.5%), low phosphate to limit biomass production, and a limitation in metal ions (zinc, copper, and iron). However, there exists one significant difference in that the sensitivity of this fungus to the formed acid, in contrast to *A. niger*, necessitates maintaining of the pH at 2.8–3.1 throughout the fermentation, in order to obtain high amounts of the acid. At present, the published production yield of itaconic acid is about 85% of theoretical, accompanied by-product concentrations of about 80 g L⁻¹ during a cultivation at 39–42°C for 8–10 days. Recovery of itaconic acid is accomplished by first separating the fungal biomass by filtration followed by evaporation, treatment with active carbon, and crystallization and recrystallization. Actual markets for itaconic acid are currently limited because the fungal fermentation is carried out at a relatively high cost. New biotechnological approaches, such as published immobilization techniques, screening programs for other producing organisms (such as yeast), and genetic engineering of *A. terreus* (the annotated genome sequence of *A. terreus* strain NIH 2624 has been publicly released), or of *A. niger*, could lead to higher production of itaconic acid. Also, the use of alternative substrates may reduce costs and thus open the market for new and expanded applications of this acid.

The high production costs for itaconic acid is still an obstacle in its more widespread use in polymer chemistry, pharmacy and agriculture. Attempts to further optimize the natural producer *A. terreus* by investigating the fermentation conditions showed that high substrate concentrations and a low pH-value under phosphate-limited conditions allow for increase in accumulation of itaconic acid to 87 g L⁻¹ after 7 days with 86% molar yield. Attempts to use metabolic engineering of the biosynthetic pathway have led to the understanding that the normal functionality of the TCA cycle results in low itaconic acid formation. The key enzyme for accumulation of itaconic acid is the *cis*-aconitate decarboxylase which requires a good precursor supply to allow for high accumulation. By the interference of the activity of pyruvate carboxylase by adding 10 mM L-aspartate, which also changed the growth morphology, it was possible to improve the itaconic acid yield by 8% and the final concentration by 60% compared to the

Fig. 18 Biosynthetic routes to itaconic acid. Reproduced from Winskill, N., 1983 Tricarboxylic acid cycle activity in relation to Itaconic acid biosynthesis by *Aspergillus terreus*. Journal of General Microbiology 129, 2877–2883, with permission from Society for General Microbiology.

control. With rigorous control of the manganese concentration in the medium, where the glucose solutions were put through an ion exchanger to lower the manganese concentration, it was possible to achieve an itaconic acid concentration of 131 g L^{-1} from 200 g L^{-1} glucose with *A. terreus*. This amount of acid is close to its solubility in water so growth at increased D-glucose concentrations of D-glucose would probably not allow for higher itaconic acid concentration.

Kojic Acid

Kojic acid (5-hydroxy-2-(hydroxymethyl)-4-pyrone, $\text{C}_6\text{H}_6\text{O}_4$) (Fig. 19) is a chelating organic acid freely soluble in water, ethanol, and acetone.

Kojic acid is a fungal metabolic product produced by a few species of *Aspergillus*, especially by *A. oryzae*, which has the Japanese common name koji. This acid is a by-product in the fermentation process of malting rice, for use in the manufacturing of sake, the Japanese rice wine.

Kojic acid was first isolated in 1907 by Saito from mycelia of *A. oryzae* grown on steamed rice. In 1912 Yabuta gave it the name kojic acid, and only in 1924 he deciphered the correct structure of the molecule of this acid.

Kojic acid is an inhibitor of growth of bacteria, fungi, and multiplication of viruses. It inhibits the catecholase activity of tyrosinase, which is rate-limiting, and an essential enzyme in the biosynthesis of the skin pigment melanin. Due to its properties as antibacterial, antioxidative, and color-protectant, kojic acid is used in the cosmetic industry, and in the food industry as a precursor for flavor enhancers (maltol and ethyl maltol), on cut fruits to prevent oxidative browning, antistaling of fruits and vegetables, and in sea food and meat to preserve pink and red colors. Kojic acid is consumed widely in the Japanese diet with the belief that it is of benefit to health (a functional food).

Kojic acid is produced chemically via pyranoid 3,2-enolones, or biologically by the direct fermentation of glucose by *A. oryzae* and *A. flavus*, where yield values of 70–90% of the acid are obtained, based on carbon source. When immobilized *A. oryzae* cells, entrapped in alginate gel beads, were used with glucose as the carbon source, kojic acid began to crystallize upon reaching a concentration of about 83 g L^{-1} . The carbon source can also be pyruvic acid, acetic acid, glycerol, and/or ethanol. The production using glucose by these filamentous fungi is very similar to that of citric acid and itaconic acid processes (i.e., at high sugar concentration and low phosphate concentration). By changing the fermentation parameters, such as stirring or aeration rate, some strains can be converted from citric acid or itaconic acid production to kojic acid production. This can be explained by the direct conversion of glucose, without splitting of the carbon chain, to kojic acid, as well as to citric and itaconic acids. By this proposed pathway, glucose is converted to D-gluconic acid by glucose dehydrogenase and D-gluconic acid is converted to kojic acid by gluconate dehydrogenase. However, direct evidence for the involvement of these enzymes in kojic acid biosynthesis has not been shown.

Research is still actively pursued to enable a biological process for kojic acid to become economical. There are attempts to use unconventional carbon sources (corn stover, cellulose) but pretreatment of the substrate is required and pentoses are inferior as C-source, fundamental drawbacks that increase the final cost. For a long time no information was available on genes responsible for kojic acid accumulation in *A. oryzae*, even though its sequence was known. Recently three genes have been isolated and described, one of them a transcription factor, all three genes are essential for the biosynthesis of kojic acid and its accumulation.

Succinic Acid

Succinic acid (butanedioic acid, $\text{C}_4\text{H}_6\text{O}_4$) (Fig. 20) is a symmetric, four-carbon, dicarboxylic acid, which forms colorless, odorless crystals with characteristic acid taste. The acid is soluble in water and slightly soluble in ethanol, ether, acetone, and glycerol.

Succinic acid (from Latin succinum, amber) was discovered in 1546 by Agricola by dry distillation (heating in vacuum) of amber.

Fig. 19 Kojic acid.

Fig. 20 Succinic acid.

Succinic acid is distributed widely through the natural world especially, in amber (3–8% by weight) and plant and animal tissues, and in microorganisms. It plays a significant role in intermediary metabolism (i.e., mainly in the TCA cycle (Fig. 2) and the glyoxylate pathway (Fig. 21).

Succinic acid is used for production of polymers, clothing fibers, plasticizers, solvents, paints, inks, food and feed additives, pharmaceuticals, perfumes, and an array of industrial and consumer products. Succinic acid is considered one of the main compounds of strategic importance as an intermediate for a multitude of applications, with the advantage that it could be produced from renewable raw materials

Succinic acid is synthesized as an intermediate of the TCA cycle (Fig. 2), operating under aerobic conditions, from α -ketoglutaric acid by α -ketoglutarate dehydrogenase. Succinic acid is an intermediate in the glyoxylate bypass (Fig. 21). Succinic acid is produced as an end product by the reductive TCA cycle (Fig. 3), under anaerobic conditions. While the biosynthesis of the acid through the first two aerobic pathways converts only four of the six carbons from glucose into the four-carbon succinic acid product, the anaerobic reductive TCA pathway produces two four-carbon acids for every glucose molecule utilized, due to the carboxylation reaction of phosphoenolpyruvate carboxylase. Therefore, anaerobic fermentations are preferred to aerobic fermentations for efficient and economical succinic acid production.

Succinic acid is produced mainly by the chemical catalytic hydrogenation of maleic or fumaric acids (about 15,000 t per year – see Table 1). Food-grade acid is probably produced through a fermentation and separation process. The market potential for products based on succinic acid (e.g., 1,4-butanediol, tetrahydrofuran, and adipic acid) is large, and, therefore, there is intensive ongoing research to develop an efficient biological route for its production.

Several biological routes to produce succinic acid are known but can as yet not compete with the chemical processes, mainly because the acid is a symmetrical molecule, similar to the fumaric acid production processes (see “Fumaric acid”). The first route is the bioconversion from fumarate to succinate, which is carried out by *Aerobacter aerogenes* strains, or by *E. coli* strains amplified for fumarate reductase. With the last bacterium, the bioconversion was shown to occur in the presence of glucose and under anaerobic conditions. A complete and rapid conversion of fumarate into succinate required high cell densities. It was found that the succinate molar yield (calculated from the utilized fumarate) was higher than 100%, suggesting that in addition to fumarate, glucose is converted to succinate. Production of succinic acid by fermentation from glucose was shown to occur by various anaerobic bacteria,

Fig. 21 The glyoxylate pathway. With permission from Dr. Paltel, R., Humboldt State University: CA, USA.

such as *E. coli*, *Enterococcus flavescens*, *Acinetobacter succinogenes*, *Anaerobiospirillum succiniciproducens*, *Mannheimia succiniciproducens*, and by the yeast *S. cerevisiae*. Succinic acid can be produced under aerobic conditions (see above) by *Fusarium* sp., *Aspergillus* sp., *Penicillium simplicissimum*, and *R. oryzae*, which excrete the acid but in rather low amounts and low yields. With *A. succinogenes* anaerobic fermentation, the succinic acid produced amounts to 110 g L⁻¹, with a yield value of 83–87% from glucose. Recent work that includes genetic engineering and immobilization techniques may improve the biological process to become competitive with the chemical process.

The industrial biomass derived production of succinic acid is well established as shown in Table 2 (reproduced with permission) where the estimates of production volumes for different companies are presented. Polybutylene succinate is one of the main predicted future products from succinate, to be used as an ecofriendly plastic, where the 1,4-butanediol is presently synthesized from acetylene and formaldehyde or from maleic anhydride. Succinic acid can also substitute for maleic anhydride as a precursor for the industrial production of butanediol, one of the large-scale chemicals that could then be derived by a biological process. The Myriant process (the largest producer listed in Table 2) as well as Reverdia use a genetically engineered yeast for succinic acid biosynthesis. In these yeasts, the reductive pathway of the TCA cycle for succinic acid accumulation have been amplified in the cytosol. In addition, since the yeasts are able to grow and produce at a lower pH (compared to the potential succinic acid producing bacteria), the free acid is formed. Accumulation of the free acid has a positive effect on the final manufacturing cost since the downstream process becomes much more straightforward. The BASF-Purac JV process is using *Bafisia succiniciproducens* with glycerol as the carbon source, whereas BioAmber initially used engineered *E. coli* but in their large-scale plants it was reported that a yeast is used. The Japanese company Ajinomoto has preferred to use the bacterium *Corynebacterium glutamicum* that was engineered to produce high succinic acid concentrations at microaerophilic conditions, with the resulting product being a salt. The reductive TCA cycle must be considered as more attractive since CO₂ is assimilated, considerably increasing the theoretical yield. It is a matter of finding the right organism with a natural or engineered reductive TCA capability and that does not produce significant amounts of byproducts and can produce succinic acid at a low pH.

5-Keto-D-Gluconic Acid

5-Keto-D-gluconic acid (5-KGA, C₆H₁₀O₇) (Fig. 22) was first obtained in 1940 by Stubbs and his colleagues, via a fermentation process.

The production from glucose of 5-KGA, and subsequently its conversion to 2-ketogluconic acid (2-KGA) (see "Ascorbic acid") (Fig. 23), is carried out by strains of the bacterium *G. oxydans*. Three different consecutive and membrane-bound periplasmic enzymes catalyze this conversion. The first enzyme is pyrroloquinoline quinone (PQQ)-dependent glucose dehydrogenase, which catalyzes the oxidation of glucose to D-gluconic acid. The second enzyme is a PQQ-dependent gluconate-5-dehydrogenase, which converts D-gluconic acid to 5-KGA. The third enzyme is a flavin-dependent gluconate-2-dehydrogenase, which converts 5-KGA to 2-KGA. This bacterium contains another set of these enzymes for the oxidation of glucose to the ketogluconic acids, which are soluble and NADP⁺-dependent enzymes. Since 2-KGA is an undesirable by-product in this fermentation, a mutant of *G. oxydans* was obtained in which the membrane-bound gluconate-2-dehydrogenase was inactivated. This mutant converted the available glucose almost completely (84%) into 5-KGA.

5-KGA can be converted effectively into L(+)-tartaric acid (see "L(+)-Tartaric acid"). The recent success in deciphering the genome of *G. oxydans* made it possible to develop a recombinant strain producing 5-KGA efficiently from glucose. This will enable the development of an economical biological process for tartaric acid, as compared to the existing process from argol, and thus increase its availability.

Table 2 Biosuccinic acid production capacity of commercial companies

Company	Annual capacity (tans)	Plant location	Operational date
BASF-Purac JV	50,000	TBA ^a	TBA ^a
BASF-PuracJV	25,000	Barcelona, Spain	2013
BioAmber-ARD	3,000	Pomacle, France	Full capacity by Q2 2012
BioAmber-Mitsui JV	65,000	TBA ^a (United States or Brazil)	TBA ^a
BioAmber-Mitsui JV	17,000	Sarnia, Ontario, Canada	2013
BioAmber-Mitsui JV	65,000	Thailand	2014

^aTBA, to be announced.

Fig. 22 5-Keto-D-gluconic acid (5-KGA).

Fig. 23 2-Keto-D-gluconic acid (2-KGA).

2-Keto-D-Gluconic Acid

2-Keto-D-gluconic acid (2-KGA, $\text{C}_6\text{H}_{10}\text{O}_7$) (Fig. 23) is used commercially as an intermediate in the production of D-isoascorbic acid (a cheap isomer of L-ascorbic acid, which is absorbed in the body and has limited antiscorbutic activity). Its accumulation by different strains of *G. oxydans*, *Acetobacter pasteurianus*, *A. aceti*, *A. cerinus*, *Enterobacter intermedium*, and *Klebsiella aerogenes* has been described. 2-KGA can be produced at high concentrations with strains of the genus *Pseudomonas* and by *Serratia marcescens*. With the latter bacterium, a fermentation process was described that resulted in 95–100% of the theoretical yield of 2-KGA from glucose.

Acrylic Acid

Acrylic acid (2-propanoic acid, $\text{C}_3\text{H}_4\text{O}_2$), (Fig. 24) is the simplest unsaturated carboxylic acid. It has both a double bond and a carboxyl group linked to its C3, and these two functional groups enable its polymerization. In its pure form, acrylic acid is a clear, colorless liquid with a characteristic acid odor. It is a major bulk chemical, being produced at over 3.4 million tonnes per year (2005, Table 1). It is miscible with water, alcohols, ethers, and chloroform. The esters and the salts of acrylic acid are collectively known as acrylates. Acrylates readily combine with themselves or other monomers (e.g., amides, acrylonitrile, vinyl, styrene, and butadiene) by reacting at their double bond, forming homopolymers (e.g., polyacrylic acid) or copolymers.

In 1843 Ferdinand Redtenbacher oxidized acrolein with aqueous silver oxide and isolated acrylic acid.

Acrylates are used in formulating paints and dispersions for paints, inks, and adhesives. Acrylates are used in manufacturing cleaning products, antioxidant agents, amphoteric surfactants, aqueous resins, and dispersions for textiles and papers. Methyl acrylate is used in making vitamin B1. Acrylate polymers have been successfully used in the manufacturing of hygienic products, detergents, and waste water treatment chemicals.

Acrylic acid is produced from propylene, a gaseous product of oil refineries, by a two-step gas-phase oxidation via acrolein. This process has almost wholly replaced alternative technologies (i.e., acrylonitrile hydrolysis and the Reppe process). In the past decade, efforts have been made to use propane, which is more widely available and even lower priced than propylene, to produce acrylic acid.

Fig. 24 Acrylic acid.

A combination of a sugar-based fermentation to produce an intermediate compound, which will then be converted by chemical catalysis to acrylic acid, provides multiple routes that may be feasible for the economical production of this acid (Fig. 25). Only one of the intermediates (e.g., β -alanine, methylcitric acid, methylmalonyl CoA, lactic acid and 3-hydroxypropionic acid), lactic acid, is commercially available today.

Dehydration of lactic acid leads directly to acrylic acid. However, when chemical catalysts were used large amounts of side-products were formed. A biological conversion of lactic acid to acrylic acid was studied in *Clostridium propionicum*, but this process has not been implemented in industry. A possible pathway of interest is shown in Fig. 26, where 3-hydroxypropionic acid is produced at a theoretical yield of 100% from glucose and is then chemically converted in a cost-effective process to acrylic acid.

Another possibility is to use the enzyme nitrilase (produced by bacteria such as *Rhodococcus rhodochrous*, *Alcaligenes faecalis*, and *Klebsiella ozaenae*) to convert acetonitrile to acrylic acid. The highest accumulation of acrylic acid, using a periodic substrate feeding strategy, was 390 g L⁻¹, with almost 100% molar conversion yield.

An engineered *E. coli* strain is able to ferment glucose directly by combining the 3-hydroxypropionic acid pathway and a novel synthetic acrylic acid pathway, but toxicity of the product and low enzyme activities are still limiting the final concentration obtained (0.12 g L⁻¹).

Adipic Acid

Adipic acid (butane-1,4-dicarboxylic acid, C₆H₁₀O₄) (Fig. 27) is a white crystalline powder of C₆-straight chain dicarboxylic acid, and is one of the most used chemicals in the world today (Table 1). It is slightly soluble in water and soluble in alcohol and acetone.

Adipic acid was first obtained by Dieterle and his colleagues in 1884 by oxidation of castor oil with nitric acid.

Adipic acid, despite its name (in Latin adipis is fat), is a product of the oxidative rancidity of fats (lipid peroxidation).

Adipic acid consumption is linked almost 90% to nylon (nylon-6,6) production by the polycondensation with 1,6-hexamethylenediamine. Adipic acid is used in manufacturing plasticizers, lubricant components, and polyester polyols for polyurethane systems. The acid and its derivatives are also used in the food industry (as gelling aid, acidulant, flavoring, leavening, and buffering reagents), and for the preparation of pesticides, dyes, textile treatment agents, fungicides, and pharmaceuticals (e.g., cephalosporin intermediates).

Fig. 25 Routes to acrylic acid from renewable carbon sources. With permission from Dr. Holladay, J., Pacific Northwest National Laboratory, WA, USA.

Fig. 26 Biosynthesis of 3-hydroxy propionic acid from glucose. With permission from Dr. Cameron, D., Koshla Ventures, CA, USA.

Fig. 27 Adipic acid.

Presently, almost all of the commercial adipic acid is produced from cyclohexane, obtained by the hydrogenation of benzene, through two sequential oxidation processes.

A plausible biological alternative can be the oxidation of cyclohexanol or cyclohexanone to adipic acid by strains of *Acinetobacter*, *Pseudomonas*, and *Xanthobacter*. The 14-kb gene cluster for cyclohexanol oxidation in *Acinetobacter* sp. contains genes encoding two alcohol dehydrogenases, an aldehyde dehydrogenase, a monooxygenase, a hydrolase, and a transcriptional regulator. A recombinant *E. coli* containing the 14-kb gene cluster was able to convert cyclohexanol to adipic acid. Theoretically, adipic acid can be produced from hexanoic acid (maybe by a *Pseudomonas* sp.), which is a product of anaerobic glucose fermentation by *Megasphaera elsdenii*. This bacterium metabolizes glucose or maltose into acetic, butyric, and hexanoic acids by serial condensations of C2 units produced from pyruvic acid. The yields of hexanoic acid are 5–8 g L⁻¹ from 40 g L⁻¹ glucose in a stirred batch fermentation. Other possibilities for the biological production of adipic acid include the production of minute amounts of the acid from aliphatic amines or diamines (e.g., dodecamethylenediamine) by *Nocardia* sp., and the conversion of straight chain monocarboxylic acids (e.g., myristic acid) into dicarboxylic acids including adipic acid by *Pichia carboniferous*. Both these biological processes are very inefficient and require substantial optimization to be competitive with the chemical process.

In the bacterium *Thermobifida fusca*, a robust thermophilic cellulolytic bacterium, it has been shown, that the use of the native occurring reversal of the adipate degradation pathway, resulted in accumulation of adipic acid with a final concentration of 2.23 g L⁻¹ using glucose as the substrate. With a more natural C-source (corn cob) the final titer was 0.22 g L⁻¹. The engineering of *E. coli* for adipic acid production condensing acetyl-CoA and succinyl CoA was much less effective with a final concentration of only 0.0007 g L⁻¹.

L-Trans-2,3-Epoxy succinic Acid

L-trans-2,3-Epoxy succinic acid (ESA, C₄H₄O₅) (Fig. 28) is a rare natural acid and it was first isolated by Sakaguchi and his colleagues in 1939, from the culture broths of *Paecilomyces variotii* and *Talaromyces flavus*. Few other fungi (such as *A. fumigatus*, *A. clavatus*, *Monilia formosa*, and *Penicillium viniferum*) produce this compound.

ESA is hydrated to meso-tartaric acid by the enzyme fumarase from pig heart and by a hydrolase obtained from *Pseudomonas putida*. ESA can be used as a good starting material for the synthesis of optically active compounds such as specific single beta-lactam antibiotics. This epoxydicarboxylic acid can be converted into dialkyltin epoxysuccinates, which are important plasticizer stabilizers for polyvinyl chlorides as well as for cross-linkable epoxy-containing film-forming polyamides.

This acid may be regarded as an oxygenation product of fumaric acid (Fig. 14), whereby the oxygen molecule is incorporated to the double bond of fumaric acid to form the epoxide carbons. Optimization of the fermentation of *P. variotii* on glucose (12%, w/v) resulted in a 41% weight yield of ESA (or 61% of the theoretical 100% molar yield).

Gallic Acid

Gallic acid (3,4,5-trihydroxybenzoic acid, C₇H₆O₅) (Fig. 29) forms white, yellowish-white, or pale fawn-colored crystals of organic acid. It is soluble in alcohol and ether but its solubility in water is low. It melts at 250°C, and above this temperature gallic acid is

Fig. 28 L-trans-2,3-Epoxy succinic acid.

Fig. 29 Gallic acid.

converted into carbon dioxide and pyrogallol. The gallic acid molecule contains two functional groups, hydroxyl groups and a carboxylic acid group, and therefore two molecules of the acid can interreact to yield numerous esters and salts, including digallic acid.

Gallic Acid was Discovered by Carl Wilhelm Scheele in 1786.

Gallic acid is found in the leaves of bearberry, in pomegranate root bark, gallnuts, witch hazel, sumac, tea leaves, oak bark, and many other plants, both in its free state and as part of the tannin molecule.

Gallic acid is utilized in the ink industry, dye industry, food industry (antioxidants and preservatives), and, most importantly, in the pharmaceutical industry (as a raw material for the production of the hallucinogenic alkaloid, mescaline, and trimethoprim, a broad-spectrum antibiotic). Upon heating, gallic acid is converted to pyrogallol or 1,2,3-trihydroxybenzene, which are used in laboratories for absorbing oxygen, and in the production of azo dyes and photographic developers.

Gallic acid is produced chemically by the hydrolysis of tannic acid by sulfuric acid at 110–120°C.

Using the free and the immobilized filamentous fungi *R. oryzae* and *Aspergillus foetidus*, solid-state or submerged fermentation processes for the production of tannase (an inducible extracellular tannin acyl hydrolase) and the hydrolysis of tannic acid extracted from tara powder (a low-priced raw material), or tannin-rich substrates, were developed. Following the extraction of gallic acid (e.g., by diethyl ether), these processes resulted in good yield of gallic acid (up to about 95% of available tannic acid), with a minimum energy input and probably more economical, as compared to the conventional industrial acid hydrolysis process.

Fatty Acids

Fatty acids are monocarboxylic acids with a long hydrocarbon chain (having the general formula $C_nH_{2n+1}COOH$), usually linear, saturated or unsaturated acids, with an even number of carbon atoms. Most of the fatty acids in nature are combined, usually with glycerol, as triglyceride in fats and, thus, these are important components of lipids in plants, animals, and microorganisms. In this article, we will focus on two classes of fatty acids: short chain fatty acids (SCFA) and polyunsaturated fatty acids (PUFA), since these are, or may be, produced by microorganisms on an industrial scale.

Short Chain Fatty Acids

SCFA, also called volatile acids, are any of a large group of monobasic acids, especially those found in animal and vegetable fats and oils, with a chain length of 2–6 carbon atoms. The major SCFA are acetic, propionic, butyric, and valeric acids. These acids are the major end products normally produced by the bacterial fermentation of dietary carbohydrates and fiber polysaccharides in the colon. These acids are considered as improved dietary components that may have a significant role in protecting against diseases. Acetic, propionic, and *n*-butyric acids account for 83% of the SCFA produced. These acids can be used in fuel production, in addition to specific other uses for each of these acids (described below). The SCFA can be produced by an active and stable mixed culture of anaerobic bacteria (e.g., initially obtained from sewage sludge digester effluent), which utilized H_2 and CO_2 (the major products from the gasification of a wide spectrum of fossil and renewable resources).

Butyric Acid

Butyric acid (*n*-butanoic acid, $C_4H_8O_2$) (Fig. 30) is a carboxylic acid, which forms an oily colorless liquid that solidifies at 8°C and boils at 164°C. It is soluble in water, ethanol, and ether. Isobutyric acid (2-methylpropanoic acid) is an isomer of butyric acid and has similar chemical properties but different physical properties (i.e., it boils at 155°C).

Butyric acid was discovered in 1869 by Lieben and Rossi. In Latin, butyric acid means the acid of butter, as it was first discovered in rancid butter (butyric acid is hydrolyzed from the glyceride and causes a very unpleasant odor).

Butyric acid is a short chain saturated fatty acid found in the form of esters in animal fats and plant oils.

Butyric acid is utilized in the production of various butyrate esters (e.g., methyl butyrate), which have pleasant aromas and tastes and are used as additives in foods, perfumes, flavorings, varnishes, pharmaceuticals, and disinfectants. It is also used for the production of plastics, plasticizers, surfactants, and textile auxiliaries. Butyric acid and its derivatives (e.g., tributyrin) are also being considered as potential anticancer agents; the acid induces cytodifferentiation of a wide variety of neoplastic cells.

Butyric acid is synthesized under anaerobic conditions from acetyl CoA, obtained from the degradation of fatty acids, or from pyruvic acid via a unique reaction catalyzed by pyruvate-ferredoxin oxidoreductase, which forms acetyl CoA, CO_2 , and H_2 (Fig. 31). Acetyl CoA is converted to butyryl CoA, which is then converted to butyric acid. Three molecules of ATP are produced per each

Fig. 30 Butyric acid.

Fig. 31 Biosynthesis of acetic, butyric, and propionic acids from glucose.

molecule of utilized glucose during this anaerobic fermentation, as compared to 2 mol of ATP produced during the production of lactic acid and/or ethanol, and 4 mol of ATP produced during the anaerobic production of acetic acid.

Butyric acid can be prepared by the chemical oxidation of butyraldehyde which has been obtained from propylene by oxosynthesis. However, the butyric acid obtained this way cannot be regarded as a natural product and, therefore, is not used in the food industry. The acid can be extracted from butter (containing 2–4% of acid) but this method is too expensive. Butyric acid is produced as end product of fermentation of sugar by obligate anaerobic bacteria, first discovered in 1861 by Pasteur; *Clostridium butyricum* being the most prominent and main bacterium, but other organisms such as *C. kluyveri*, *C. beijerinckii*, *C. barkeri*, *C. acetobutylicum*, *C. thermobutyricum*, *C. thermopalmarium*, *C. pasteurianum*, *Butyribacterium* sp., *Sarcina* sp., *Megasphaera* sp., *Fusobacterium nucleatum*, *Peptococcus asaccharolyticus*, *Butyrivibrio fibrisolvens*, *Pseudobutyrvibrio ruminis*, and *Eubacterium limosum* are also used. Optimal cultivation conditions are 35–37°C, an atmosphere of pure CO₂, N₂, and a pH range of 4.5–7.0. The *Clostridia* can utilize hexoses, several pentoses, and polysaccharides. Butyrate production is favorable in a fed-batch, glucose-limited, and slow-growing culture. It is also stimulated under phosphate and nitrogen limitation. Batch, fed-batch, or continuous processes combined with cell recycle or immobilization are applicable for these anaerobic fermentations. Inhibition of the fermentation caused by the butyric acid formed can be avoided by the on-line removal of the acid by various methods (e.g., distillation and evaporation, permeate electrodialysis, and adsorption). Butyric acid can also be removed by extraction, or by extraction combined with simultaneous stripping of the organic phase (liquid membrane) into the second aqueous phase (pertraction).

The amount estimated in 2013 for the volume of butyric acid produced is 80,000 t per year, made by chemical synthesis by oxidation of *n*-butyraldehyde, synthesized from propylene. To allow for an economical biological process efforts to use biomass (lignocellulose) both with mixed and axenic cultures (*Clostridium*) are under active investigation. All known fermentation set ups, ranging from batch and fed-batch to continuous fermentations with and without cell recycling, have been evaluated for butyrate production. The concentrations achieved are still too low to be competitive with the chemical synthesis. Use of immobilized adapted *Clostridium tyrobutyricum* in a fibrous bed reactor allowed for high concentrations of butyric acid to accumulate (86.9 g L⁻¹). There is still a need to further increase the butyrate tolerance in the prospective producing strains. Butanol, the alcohol derivative of butyric acid, is considered one of the future biomass fuels. Butyric acid may be used as a precursor for butanol manufacture since the

butyric acid tolerance is at least 5 times better in the producing organisms compared to the concentration of butanol that is tolerated by its producing organisms.

Propionic Acid

Propionic acid (propanoic acid, $C_3H_6O_2$) (Fig. 32) is a naturally occurring three-carbon carboxylic acid. In the pure state, it is a colorless, water soluble, and corrosive liquid with a sharp, somewhat unpleasant odor.

Propionic acid was first described in 1844 by Johann Gottlieb, who found it among the degradation products of sugar. Its name is derived from the Latin words *protos* and *pion*, which mean first and fat, respectively.

Propionic acid is used in the manufacture of herbicides, fine chemical intermediates, rubber chemicals, emulsions, and environmentally friendly solvents for coating formulations, artificial fruit flavors, pharmaceuticals, and modified synthetic cellulose fibers (e.g., cellulose acetate propionate). Propionic acid inhibits growth of mold and various bacteria and is used as a preservative for food (especially bread and other baked goods as its sodium or calcium salts), animal feed (directly or as its ammonium salt), and grains.

Propionic acid is biosynthesized as propionyl CoA, which is a product of the catabolism of fatty acids having odd numbers of carbon atoms, and of the degradation of some amino acids. Propionic acid bacteria (e.g., *Propionibacterium shermanii*) produce this acid as a product of their anaerobic metabolism of sugars. The initial catabolism of glucose to pyruvic acid follows glycolysis, and the NADH formed is oxidized via a pathway by which propionic acid is produced. Pyruvic acid accepts a carboxyl group from methylmalonyl CoA by a transcarboxylase reaction, leading to the formation of oxaloacetic acid and propionic acid (Fig. 31). *Propionibacterium* sp. (and other bacteria such as *C. propionicum*, *M. elsdenii*, and *Prevotella ruminicola*) also ferments lactic acid with the production of propionic acid, acetic acid, and CO_2 (Fig. 31).

Commercial production of propionic acid is mainly carried out via chemical synthesis from petroleum feedstocks by three process routes: ethylene hydroformylation/oxidation, carboxylation of ethylene with carbon monoxide and water, and direct oxidation of hydrocarbons. Propionic acid is also produced, in minor quantities, as a by-product of acetic acid manufacturing.

Fermentation is an attractive route to produce this acid from renewable sugars (such as glucose, xylose, maltose, sucrose, and lactose) by propionic acid bacteria (e.g., *P. shermanii* and *P. acidipropionici*). These bacteria play important roles in the dairy industry in the development of the characteristic flavors and holes (or eyes) production (by CO_2 evolution) in Swiss-type cheese. However, this fermentation process is inefficient and only barely competes with the chemical processes for the production of propionic acid. The fermentation parameters that affect the cost of the fermentation process are the low rates and the maximal amounts of the product, and the formation of undesirable by-products in addition to propionic acid. Thus, only small amounts of this acid are produced by fermentation of whey and are used as a natural product in foods to adhere to the labeling rules of natural foods. Since the genome sequence of *Propionibacterium freudenreichii shermanii* ATCC9614 is being almost completed, it may be conceivable that the fermentation route could become economically valuable. Propionic acid can also be obtained by oxidation of propanol with *G. oxydans*, in a fed-batch fermentation process, resulting in 56 g L^{-1} of the sodium propionate (the yields of the acid obtained are near the theoretical values) after 70 h. Since the bacterium cannot grow on propanol as a sole carbon source, but is able to convert it to propionic acid, glycerol was used as an assimilable cosubstrate.

The biological production of propionic acid has not been realized due to the low productivity, yield and product purity obtained; even with metabolically engineered strains of *Propionibacterium* it cannot challenge the chemical process. The experiments described in the public space are at a small scale, either shake flasks or small laboratory fermentors. One report describes the use of a 10 m^3 vessel where 47.3 g L^{-1} propionic acid was obtained after 240 h in a glycerol fed-batch culture fermentation. Glycerol is considered an ideal substrate for the production of this acid since glycerol is more reduced than glucose and therefore beneficial in the production of reduced chemicals. Use of glycerol also reduces the accumulation of acetic acid a common by-product when glucose is used as a carbon source.

Valeric Acid

Valeric acid (pentanoic acid, $C_5H_{10}O_2$) (Fig. 33) is a straight, saturated chain, alkyl carboxylic acid. It is a colorless, oily liquid with a very unpleasant odor of stale cheese. The acid exists in four isomeric forms, one of which contains an asymmetric carbon atom and consequently occurs in two optically active modifications and one optically inactive modification.

Valeric acid is found naturally as free or as esters in the vegetable and animal kingdoms.

Valeric acid, and its esters, is mainly used in perfumes and cosmetics, as food additives because of the fruity flavor of the esters, and as plasticizers and pharmaceuticals.

Valeric acid can be extracted by boiling water or soda from the roots of *Angelica archangelica* and *Valeriana officinalis* (from which valeric acid gets the name). The acid can also be obtained by oxidizing fermentation amyl alcohol with chromic acid. The acid can be

Fig. 32 Propionic acid.

Fig. 33 Valeric acid.

formed by microorganisms during the anaerobic fermentation of CO_2 and H_2 (discussed above) and by the fermentation of other carbon sources, such as wastewater solids.

Polyunsaturated Fatty Acids

PUFA are fatty acids in which more than one double bond (generally separated by a single methylene group) exists within the representative molecule. The term PUFA is used only for acids with three up to six double bonds as those found in fish oil or brain tissue. These acids (also called essential fatty acids (EFAs)) are necessary fats that humans cannot synthesize, and must be obtained through their diet. There are two families of EFAs: omega-3 and omega-6 fatty acids, in which the position of the first double bond, from the terminal methyl group of the molecule, is indicated by the number following 'omega'.

There is a great variety of polyunsaturated fatty acids, and here we will discuss those that are of commercial interest and possible to produce by microorganisms, namely, arachidonic acid, $\text{C}_{20}\text{H}_{32}\text{O}_2$ (ARA) (Fig. 34); γ -linolenic acid, $\text{C}_{18}\text{H}_{30}\text{O}_2$ (GLA) (Fig. 35); and docosahexaenoic acid, $\text{C}_{22}\text{H}_{32}\text{O}_2$ (DHA) (Fig. 36).

Microbial lipid production is of interest when the desired fatty acids are difficult to obtain from plant or animal oils. The formation of fatty acids for commercial purposes is called single-cell oil (SCO). Prokaryotes are known to form a variety of fatty acid structures including, branched chains, cyclopropane rings, and *trans*-double bonds, whereas eukaryotes only form straight chains with *cis*-double bonds. The fatty acids of interest (ARA, GLA, and DHA) are all straight chains containing solely *cis*-double bonds and with methylene interruption ($\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}$). Most microorganisms do not accumulate triacylglycerol lipids and their main lipid is in the form of phospholipids. Microorganisms that do accumulate more than 20% of their dry weight as triacylglycerol lipids are called oleaginous and are of commercial interest. Fatty acids are important for both structure and storage, and also as precursors for a range of cell signaling molecules, involved in inflammatory responses, blood coagulation, and reproductive function. ARA and DHA are of particular interest, since they are common in neural tissues both of the eye and of the brain. They are both present in human breast milk and are added to infant formula in more than 60 countries, with beneficial effects on visual and intellectual development.

In 1985, the first commercial process growing the fungus *Mucor circinelloides* for SCO was started in Japan. The fungus was grown in stirred-tank fermentors followed by extraction of the oil and final refinement and purification. The product was rich in GLA (18–20% of the oil) and was produced for 6 years when the introduction of plant-derived 'borage oil' became a cheaper source of GLA. γ -Linolenic acid is now obtained primarily from the seed of the evening primrose plant.

In case the dietary requirement is for a single acid, this is best met by microbial oil, which has lead to renewed commercially successful production from 2000. Three organisms are in use for DHA production, *Cryptocodinium cohnii*, *Schizochytrium* sp., and *Ulkenia* sp., all grown by submerged fermentations. ARA was shown to be a major component of the oil from *Mortierella alpina*. Various strains of *M. alpina* are used in processes in Europe, China, and possibly also in Japan.

PUFA materials are introduced as dietary supplements for adults especially as DHA-rich oils, to help prevent coronary heart problems. There are also suggestions that DHA may be useful as a dietary supplement to prevent the onset of degenerative disorders such as Alzheimer's disease.

Fig. 34 Arachidonic acid (ARA).

Fig. 35 γ -Linolenic acid (GLA).

Fig. 36 Docosahexaenoic acid (DHA).

The commercial production of PUFA is profitable, with an estimated production volume of over 3000 t of DHA produced annually from either fungi or algae. Already in 1985–1990 gamma linolenic acid was produced with the filamentous fungi *Mucor circinelloides* by J&E Sturge in 220 m³ fermentors. However, the fungal product was outcompeted in a price war by the plant derived Evening Primrose Oil. Some of the companies known to be involved in the production of PUFAs today are among others the Dutch company DSM using the Martek developed technology with a combination of DHA from the microalgae *C. cohnii* and ARA from the filamentous fungi *Mortierella alpina*. The mixture of the two acids inhibits the degradation of DHA that occurs if ARA is not present. CABIO a subsidiary of Cargill operating in China also utilizes a strain of *Mortierella alpina* and the Swiss company Lonza using the algae *Ulkenia*. At DuPont the yeast *Y. lipolytica* engineered with at least 15–20 genes is able to accumulate eicosapentaenoic acid that has obtained a GRAS status from the FDA.

Conclusions

As is evident from this article, there is a strong competition, based mainly on economical considerations, between the chemical and the fermentation industries to produce organic acids. At the present time, chemical processes, being more economical than the fermentation processes, are the existing industrial manufacturing processes not only for symmetrical molecules (e.g., fumaric acid and succinic acid) but also for asymmetrical molecules (e.g., malic acid). Unlocking the biochemical networks and the regulatory mechanisms of the producer strains, and implementing modern technologies of genetic and metabolic engineering (e.g., global transcription machinery engineering, systems biology) may provide an opportunity for their manipulation by amplifying or deleting critical steps in metabolism to improve acid production or to overproduce novel acids. In addition, the newly emerging information will allow the efficient production of acids (e.g., L-lactic and succinic acids) by a better suitable and specifically tailored microorganism (e.g., *A. niger*) under different production conditions (e.g., microaerophilic or aerobic instead of anaerobic conditions). These approaches may be a major breakthrough in the scientific methodology that can improve considerably the economy of industrial processes employing biological systems for the production of acids.

The use of metabolic engineering and omics technologies allow for fundamental changes in both natural producing organisms as with platform organisms. In some cases, it has been possible to show proof of concept where novel acids are produced by former non-producers. The challenge that remains is to optimize the conditions to allow for concentrations that can be competitive with the current chemical processes.

Origin of Life, Theories of

William F Martin and Martina Preiner, Heinrich Heine University, Düsseldorf, Germany

© 2017 Elsevier Inc. All rights reserved.

There are many facets to the problem of understanding life's origin and equally many ways to address it. The origin of life can be viewed from a variety of different standpoints: information theory (Yockey, 2005), RNA replication (Eigen and Schuster, 1977), meteorite impacts (Brack, 2009), physics (Smith and Morowitz, 2016), specific chemical synthesis (Powner et al., 2009), geochemistry (Martin and Russell, 2003), or entropy (Russell et al., 2013), to name a few. Common to all current theories for the origin of life is the view that some kinds of molecules, probably similar to nucleic acids, were able to replicate and undergo selection for the ability to replicate prior to the advent of fully fledged free living cells.

When it comes to addressing the origin of life as we know it, as opposed to considering forms of life that are imaginable, it is helpful to connect ideas on the origin of life with the biology of modern microbes. This constrains the thoughts on the topic from becoming too theoretical or otherwise decoupled from life (that which is to be explained). The properties of life and the nature of living things focus thoughts about how or where life might have been arisen. Understanding which forms of life among the many that we know are likely to be the most primitive is also important in understanding life's origin, because it helps to narrow down the many possibilities when it comes to trying to narrow the gap between spontaneous chemical processes on the early Earth and biological processes in microbes with primitive metabolism. In the literature on the origin of life, four attributes of life recurrently come up as central to the issue: compartmentation, information, replication, and energy.

Compartmentation

Because all life that we know is organized as cells, there is every reason to assume that the first forms of life were also cellular. It also means that in the time before there were fully fledged free-living cells, there were simpler entities that were not capable of independent replication in the wild (Ganti, 1975). Compartmentation is important for two reasons. First, whatever chemical synthesis one has in mind for the synthesis of life's building blocks, some kind of concentrating mechanism or barrier has to exist such that the products of synthesis do not diffuse off into the oceans (Kuhn, 1972). Second, for any form of evolution to take place among replicating molecules, the population of molecules has to be structured in some manner in order to permit selection to act. That is, selection for new populations of molecules with new and different properties, for example, a catalytic activity or efficiency of replication, cannot occur unless the molecular populations are distinct. In an unstructured population of molecules, the fastest replicators, also called parasites, will prevail (Branciamore et al., 2009). There are various thoughts about how early molecular systems might have been compartmentalized from the environment to permit concentration and selection, these include evaporation on land, freezing in ice (eutectic mixtures), or naturally forming inorganic compartments at hydrothermal vents (Martin and Russell, 2003).

Information

All forms of life have the universal genetic code. It is therefore reasonable to assume that a form of information processing that involves the modern genetic code was also present in the very first forms of life as well. That is consistent with the observation that the genetic code is one of the oldest and least modified traits of life as we know it (Wong, 1975). The genetic code is quite complex. It requires the accurate loading of coding amino acids onto tRNA, tRNA-mRNA interactions mediated by the ribosome (and ribosomal RNA). It is likely that earlier forms of the code were simpler than the modern code, using a two letter code, for example, rather than three letter triplets. The issue of how the code arose is an unresolved problem (Koonin and Novozhilov, 2009), although theories strive to link the origin of the code to metabolism by suggesting that the amino and oxygen moieties in the bases of the tRNA anticodon provided catalytic activity that synthesized the cognate amino acid on the tRNA acceptor stem, as opposed to linking preformed amino acids with tRNA (Copley et al., 2007).

Replication

Replication has long been viewed as one of the most important aspects at life's origin. For anything to evolve in a Darwinian sense, it must generate copies of itself that differ to some degree from the original (natural variation) and exhibit properties that would permit their differential success in a proliferation sense (natural selection). Since the pioneering work of Sol Spiegelman and Manfred Eigen with a viral enzyme called Q β replicase, replication of RNA has stood in the foreground of thinking on the issue (Spiegelman, 1965; Eigen, 1971). RNA can be replicated (like DNA) and can exhibit catalytic activity (proteins) making it attractive as a precursor to both in evolution. Eigen's work in particular demonstrated the differential success of different RNA templates to replicate in vitro. That established the concept of natural variation and natural selection among molecules prior to the origin of variation and selection among cells. This aspect, in addition to replication plus catalysis, gave rise to the concept of evolution in an

This article is a reprint of William F. Martin, Martina Preiner, Origin of Life, Theories of, *Reference Module in Life Sciences*, Elsevier, 2017.

RNA world that preceded the evolution of cells (Gilbert, 1986). RNA evolution experiments are widely conducted under laboratory conditions (Lincoln and Joyce, 2009). However, on the early earth, the chemical environment was harsh. There were only rocks and water, there was the constant threat of diffusion into the ocean, UV light was abundant, as was constant meteorite impact and widespread volcanic activity. Such conditions have little if any similarity with modern laboratory conditions, a circumstance that acts as a kind of watershed in origin of life theories as concerns the role of RNA. Proponents of the RNA world point to the experimental accessibility of RNA replication as a model for early evolution, while geochemists point to the lack of known environmental conditions that would allow an RNA world to arise or evolve.

Part of the replication aspect of origins concerns speed. The fastest replicators will incorporate all environmentally available monomers into polymeric likenesses of themselves, thereby greedily consuming all available resources. Hence they will survive much better and dominate under molecular selection schemes than other sequence variants (stability to hydrolysis being equal among different sequences). But a fast replicating sequence variant might mutate so as to generate even faster variants, in which case they would outcompete the slower ancestor and follow an evolutionary trajectory toward the fastest replicating sequence. Once that locally optimal, fastest replicating sequence has evolved, mutational variants drift away from the optimum and generate slower replicating progeny while cluttering the sequence space (the sum of all possible sequence variants around the fastest replicator). That concept of a locally optimal replicator and its less optimal variants was developed by Eigen in the context of replication; such a replicator together with its variants is called a quasispecies (Eigen and Schuster, 1977).

Energy

Perhaps most essentially, all forms of life harness one or more sources of energy that are available in the environment. No form of replication or selection or evolution among either molecules or cells can take place without energy release hence energy supply, as stipulated by the second law of thermodynamics. As a consequence of that constraint, we can be rather certain that prior to the advent of biological cells, prebiotic chemical reactions had to occur spontaneously. All spontaneous chemical reactions entail, in turn, an overall exergonic reaction that supplies the free energy change needed for the reaction to take place (Thauer et al., 1977). This does not mean that every single reaction in prebiotic evolution had to be exergonic. Many reactions in modern metabolism are endergonic. But endergonic reactions are necessarily coupled to a main energy releasing reaction that the cell harnesses in order to drive metabolism and the life process forward. In modern metabolism, the most widespread form of coupling is through adenosine triphosphate (ATP). ATP hydrolysis releases energy, such that endergonic reactions can be coupled (enzymatically) to ATP hydrolysis such that the overall reaction is energetically downhill and will thus go forward (Sousa and Martin, 2014). There are other forms of energy currencies in metabolism besides ATP, these include thioesters (Goldford et al., 2017), acyl phosphates (Schönheit et al., 2016), and reduced ferredoxin, a small soluble iron–sulfur cluster containing protein that transfers low potential electrons in metabolism (Eck and Dayhoff, 1966). These currencies are synthesized in what biologists call energy metabolism (the main bioenergetic reaction of the cell), and are used to drive other reactions forward. At the origin of life, there must have been some sort of energy supply that drove the synthesis of organic compounds forward to a level where complex polymers (peptides and nucleic acids) were formed. Among the possible sources of environmental energy most often discussed are ultraviolet light, lightning, heat, and chemical energy (Kaufmann, 2009). If we look around among anaerobic chemoautotrophic microbes, only chemical energy is harnessed for energetic coupling.

As seen from the standpoint of biology, life is a side product or a byproduct of the main energy releasing (exergonic) reaction that serves to drive all other reactions in the cell forward. Put more succinctly, life is an exergonic chemical reaction. The synthesis of the very first chemical components of which cells are composed, often called the building blocks of life, must also have been the products of exergonic reactions, because the second law of thermodynamics stipulates that chemical reactions can only go forward if the overall reaction releases energy.

Molecular Networks

Living cells are side products of a main energy releasing reaction. Stated another way, metabolism generates life, not vice versa; the main flux of carbon, energy, and nutrients through the cells generates the substance and organization of cell mass. For example, acetogens channel 24 molecules of CO₂ through the cell as waste product (acetate) for every molecule of CO₂ that they incorporate into cell carbon (Daniel et al., 1990). One of the longstanding puzzles in the origin of metabolism is the emergence of biochemical networks. Recent progress on that topic has come from the investigation of autocatalytic networks (Hordijk and Steel, 2004; Hordijk et al., 2012), which have shown that the elements of a chemical network need not provide much catalysis for other steps in the network in order for flux through the system, hence net synthesis of the system itself, to increase. In the laboratory, chemical networks with oscillatory properties have been constructed, using thioesters as the chemical energy source (Semenov et al., 2016).

Two Main Theories for Carbon

As recently summarized elsewhere (Schönheit et al., 2016), a convenient structure to the problem is obtained if we sort theories on the origin of life into two categories based upon the assumptions they entail regarding the nature of carbon metabolism in the

earliest cells. By that criterion, theories about the earliest phases of evolution fall into two main categories: autotrophic origins versus heterotrophic origins. Theories for autotrophic origins posit that the first cells fulfilled their carbon needs from CO₂. Heterotrophic origin theories are based on the idea that the first cells lived from the fermentations of reduced organic compounds present in some kind of rich organic soup. The main contours of the two theories as they interface with biology can be summarized briefly.

Heterotrophic Origins

Heterotrophic origin theories are traditionally favored by chemists (Bada and Lazcano, 2008; Miller and Orgel, 1974; Orgel, 2008). Seen from a biological perspective, heterotrophic origin theories have two main drawbacks. First, they do not connect with the chemistry of modern cells. They start with cyanide (Levy et al., 1999), formamide (Saladino et al., 2012), or UV light-dependent (Ritson and Sutherland, 2013) condensations. The conditions underlying heterotrophic origin theories are sometimes viewed by geochemists as unlikely to ever have existed on early Earth (McCollom, 2013). Organic compounds delivered from space are seen as a source of carbon for the first cells in some heterotrophic origin theories, however, carbon from space is an unfermentable substrate and is furthermore chemically too heterogeneous to have served as a carbon source for the first cells (Schönheit et al., 2016).

Autotrophic Origins

Autotrophic origin theories, by contrast, generally operate with chemicals that undoubtedly did exist on the anaerobic early Earth: H₂, CO₂, N₂ and H₂S. Transition metals and transition metal sulfide (FeS and FeNiS) centers play a crucial role in autotrophic origin theories for several reasons. First, FeS and FeNiS centers serve as essential catalysts in the modern day core carbon and energy metabolism of anaerobic autotrophs, as such they provide direct links between the origin of life and modern cells (Eck and Dayhoff, 1966). Second, FeS and FeNiS minerals abound in anaerobic geological settings both today and on the early Earth (Wächtershäuser, 1992). Third FeS and FeNiS centers are naturally catalytic by virtue of their unfilled d and f electron orbitals, which can readily hybridize to generate metastable bonds with carbon and nitrogen. Under the theory of autotrophic origins the first cells satisfied their carbon needs from CO₂ (Schönheit et al., 2016).

Serpentinization

In recent years, geochemical processes in modern hydrothermal vents have been characterized that resemble biological processes germane to autotrophic origin theories. This development can perhaps be best summarized with the main keyword “serpentinization” (Russell et al., 2010). During serpentinization, water is drawn by the force of gravity into cracks in the Earth’s crust. At depths of one to several kilometers and temperatures around 200°C, water reacts with Fe²⁺ in the iron–magnesium silicates that comprise the crust. Water is thereby reduced to generate molecular H₂. The effluent of hydrothermal systems can contain up to 10 vol% or more H₂ (Etiope et al., 2011). H₂ is a useful currency of chemical energy for many modern microbes, in particular for anaerobic autotrophs.

Geochemists have also discovered a modest variety of chemical reactions that are occurring naturally at hydrothermal vents today that entail the synthesis of methane (CH₄) and other small molecular weight carbon compounds such as formate and short chain hydrocarbons within hydrothermal systems (Schrenk et al., 2013; McDermott et al., 2015; McCollom, 2016). Methane can be present in the effluent of hydrothermal vents at up to 2 mmol kg^{−1} (Schrenk et al., 2013) and can constitute up to 87 vol% of the vent gas emission (Etiope et al., 2011), hydrocarbons in much lower amounts, formate has only been reported for some systems (Schrenk et al., 2013). The mechanism of methane synthesis in hydrothermal systems is still uncertain (McCollom, 2016). It might entail reduction of dissolved CO₂ or of rock-bound carbonate. Whether H₂ or reduced transition metal species in the crust are the source of electrons for CO₂ reduction is not known.

Some modern microbes called methanogens belonging to the domain archaea synthesize methane from H₂ and CO₂ or C₁ compounds (Thauer et al., 2008; Mayumi et al., 2013). To determine whether the methane produced in hydrothermal vents is of biological (methanogenesis) or of geochemical (serpentinization) origin, geochemists use stable isotope ratios that involve measuring the ¹³C/¹²C and ²H/¹H ratios of the respective compounds. Such measurements cannot be fully explained here; let it suffice to say that the ¹³C/¹²C and ²H/¹H isotope signatures of methane produced by biological and geological processes can be distinguished, geochemically produced methane being typically enriched in the heavier carbon isotope and depleted in the heavier hydrogen isotope relative to biogenically produced methane (Etiope et al., 2011; Pedrera et al., 2016). In laboratory scale serpentinization reactions, acetate and formate synthesis has been reported (Miller et al., 2017).

Ancient Microbial Lineages

Various lines of evidence suggest that anaerobic autotrophs are the most ancient lineages among microbes known today. Modern anaerobic autotrophs thrive upon H₂, which is continuously generated in serpentinizing geological settings at activities of the order

of 10 mmol kg⁻¹ or more via disequilibria driven by rock–water interactions in hydrothermal systems. At such high H₂ activities, and under strictly anaerobic conditions, the synthesis of cell mass from CO₂ is thermodynamically favorable. The core pathway of carbon and energy metabolism in anaerobic autotrophs that inhabit such hydrothermal and deep crust environments is the acetyl-coenzyme A (CoA) pathway, the most ancient of the six pathways of CO₂ fixation known (Fuchs, 2011) and the only one present in archaea and bacteria.

The observation that spontaneous exergonic organic syntheses from H₂ and CO₂ occur today at hydrothermal vents suggests that these processes are similar, if not homologous (Martin, 2012), to core energy-releasing reactions of carbon and energy metabolism in methanogens (Thauer et al., 2008) and acetogens (Schuchmann and Müller, 2014), which live from the reduction of CO₂ by H₂. Chemists are less taken by the similarity of the overall exergonic processes and tend to doubt in rather general terms that there are any traces of ancestral metabolic processes retained in any modern metabolic pathways (Orgel, 2008). However, the evidence is fairly solid that microbial communities have been thriving in hydrothermal vents for over 3.3 billion years (Westall et al., 2012). From the biological standpoint, there is no strong a priori reason to assume that the energy releasing reactions from which those ancient microbes harnessed energy were fundamentally different from those that modern anaerobes living in the same environment use (Martin and Sousa, 2016). From the geochemical standpoint, there is no clear indication that early biological processes were fundamentally different from those still existing today in anaerobic environments (Arndt and Nisbet, 2012). Investigations of microbial genomes support the view that the first cells lived from H₂ and CO₂ and that acetogens (bacteria) and methanogens (archaea) are among the most primitive prokaryotic lineages currently known (Weiss et al., 2016).

Glossary

β -barrel A protein-folding pattern in which an extensive β -sheet structure closes upon itself, producing a cylinder or a barrel structure.

Bile salts Amphiphilic derivative of cholesterol secreted in bile and functioning as detergents for the digestion of fat in the intestinal tract. Conjugated bile acids often have strongly acidic groups (for example from taurine).

Kdo An acidic, eight-carbon sugar 2-keto-3-deoxy-octonate or 3-deoxy-D-mannooctulosonate.

Lipid bilayer An ordered two-layered arrangement of polar lipids so that their lipophilic portions associate in the center and their polar head groups face the outside.

Lipopolysaccharide (LPS) A complex polymer comprising the outer leaflet of the outer membrane bilayer. Its polysaccharide portion acts as a major antigen, and its lipid portion (lipid A) is responsible for its endotoxic activity.

Molecular chaperone A protein that helps the folding of nascent proteins by binding to unfolded or misfolded polypeptides.

Peptidoglycan (murein) An extensively cross-linked structure unique to bacteria, preventing the bursting of the cytoplasm by acting as a mechanically strong cage.

Periplasm The space between the cytoplasmic membrane and outer membrane, containing peptidoglycan, membrane-derived oligosaccharides (MDO) and many unique proteins.

Porin An outer membrane protein that allows the non-specific transmembrane diffusion of small, hydrophilic solutes.

R LPS An incomplete lipopolysaccharide containing only the lipid A and the core portion of the saccharide chain, devoid of the O chain. So named because it is produced by mutants that show a "rough" (R) colony morphology.

SecYEG A multiprotein export apparatus in bacteria, responsible for the transmembrane export of most proteins, including periplasmic and outer membrane proteins.

Sigma factor A subunit of bacterial RNA polymerase that recognizes a specific set of promoter sequences.

Toll-like receptor Transmembrane receptors on animal cell surface, which recognize various common components of microbial pathogens. So named because of its similarity to the Toll receptor in *Drosophila*.

Two-component system A signal transduction pathway widespread in bacteria, which consists of a histidine kinase sensor and a response regulator that becomes activated by the phosphorylation of its aspartate residue.

The Cell Envelope of Gram-Negative Bacteria

The cell envelope of gram-negative bacteria contains, in addition to an inner, cytoplasmic membrane, an outer membrane, a structure unique to organisms of this group. The space between the two membranes is the periplasm, where we find not only the peptidoglycan (murein) cell wall but also many unique proteins. The outer membrane acts as a protective barrier, limiting the access of noxious compounds present in the environment. The enteric bacteria, especially *Escherichia coli* and *Salmonella*, served as a paradigm for the studies of structure and function of the outer membrane.

Composition, Structure, and Functions of Outer Membrane

Lipids and Lipopolysaccharides

Outer membrane is distinctly different from the inner, or cytoplasmic membrane in terms of composition. The lipid bilayer domain, which is composed of mainly glycerophospholipids (phosphatidylethanolamine, phosphatidylglycerol, and cardiolipin in the enteric bacteria) in the inner membrane, here contains in addition a characteristic component, lipopolysaccharide (LPS). LPS is composed of two domains – the lipophilic lipid A domain and the hydrophilic polysaccharide domain. A single lipid A domain contains 5–7 fatty acid residues, all saturated and usually containing a 3-hydroxyl group, in contrast to just two often unsaturated fatty acid residues found in phosphatidylethanolamine (Fig. 1) or phosphatidylglycerol. The lipid A head group is based on a phosphorylated glucosamine disaccharide, in contrast to the glycerol phosphate moiety in the glycerophospholipids. It is also connected to a polysaccharide structure, which protrudes into the external medium and plays a major role in the interaction of bacteria with the external world.

This article is an update of H. Nikaido, Outer Membrane, Gram-Negative Bacteria, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 439–452.

Fig. 1 Structure of lipid A and phosphatidylethanolamine. For the latter, the most abundant species in *E. coli*, containing palmitate (C16:0) and *cis*-vacenate (C18:1) at 1- and 2-position, respectively, is shown.

Fig. 2 A model of the outer membrane of enteric bacteria. In the bilayer domain, the outer leaflet is composed exclusively of lipopolysaccharides, the inner leaflet glycerophospholipids. A non-specific porin is also shown.

Fig. 3 Structure of the polysaccharide portion of LPS. The figure shows, as an example, the LPS of *Salmonella typhimurium* (*Salmonella enterica* serovar Typhimurium). In this species the O chain is composed of a repeating unit, containing a 3,6-dideoxyhexose, abequose. The more proximal part of the core may contain additional residues in non-stoichiometric amounts, shown in non-bold letters. Abbreviations: Abe, abequose; Rha, L-rhamnose; Man, α -mannose; Gal, α -galactose; Glc, D-glucose; GlcNAc, N-acetyl-D-glucosamine; Hep, L-glycero-D-mannheptose; Kdo, 3-deoxy-D-mannoctulosonate; P, phosphate; (P)PE, (pyro)phosphorylethanolamine.

In *E. coli* and *Salmonella*, the entire outer leaflet of the bilayer appears to be composed of LPS, the phospholipids occupying only the inner leaflet (Fig. 2). This asymmetric structure produces an exceptionally impermeable bilayer. Lipid bilayers can usually be penetrated easily by lipophilic molecules, including various drugs, because these molecules can dissolve into the interior of the membrane, and redissolve in the aqueous phase on the other side of the membrane. However, the rate of such permeation is about two orders of magnitude slower across the outer membrane bilayer. This is caused by the very low fluidity of the interior of the LPS leaflet, which in turn is the result of the presence of only saturated fatty acids, of many fatty acid chains connected covalently to a single head group, and of the bridging, by divalent cations, of neighboring, negatively charged, LPS molecules (see below). Thus the LPS and the LPS-containing outer leaflet of the outer membrane play a major role in producing an effective permeability barrier against the entry of lipophilic compounds, including many antibiotics. Isoxazolylpenicillins (such as oxacillin), macrolides (such as erythromycin), and rifamycins show little activity against gram-negative bacteria yet show strong activity against gram-positive bacteria; this limited range is to a large extent due to the low permeability of the LPS leaflet.

The polysaccharide portion of LPS (Fig. 3) is usually divided into the “core”, which is connected to lipid A, and “O side-chain”, which in turn is connected to the core. The core is composed of a non-repeating oligosaccharide structure, which contains numerous acidic groups especially in its inner portion, close to the head group of lipid A. The glucosamine disaccharide head group also carries phosphate or pyrophosphate groups at both ends. Thus the inner portion of LPS core has a very high density of negative charges, which are usually neutralized by divalent cations, such as Mg^{2+} and Ca^{2+} , in living bacterial cells.

The O-chain is most often composed of an oligosaccharide repeat unit, which frequently contains unusual sugars like 3,6-dideoxyhexoses. Since this is the portion that is exposed to the external world, animal pathogens will induce the production of antibodies that bind this portion of LPS. If the repeating unit contains unusual sugars, this may help the bacteria to evade the antibodies prevailing in the population of higher vertebrates. The structure of O-chain has thus undergone extensive modifications during recent evolutionary history, so that serological analysis has shown the presence of more than 100 types of O chains (recognized as “O antigens”) in *E. coli* alone.

Our body recognizes the lipid A domain of LPS as a characteristic common component of a pathogen, through the Toll-like receptor on the surface of many cells, and this results in the strong stimulation of specific immune response that follows. Thus this reaction is meant to help protect our body from infection, and some successful human pathogens are known to modify the lipid A structure in order to avoid the recognition by the host. Yet the recognition of lipid A domain by the Toll-like receptor can result in the overstimulation of many cells in our body, when many molecules of LPS are suddenly introduced, for example, by injection. Because of this reaction, LPS is also known as “endotoxin”. Humans and rabbits are some of the most susceptible animals to endotoxin, and even 1 ng/kg body weight will cause significant increases in body temperature. A large amount of LPS is released into blood stream from dying bacteria, when patients suffering from sepsis (multiplication of bacteria in the blood stream) are treated by an effective antibiotic. This often causes severe, often fatal shock reactions (septic shock) in patients.

In addition to LPS, the outer membrane of the enteric bacteria contains enterobacterial common antigen (ECA). Unlike the O antigen polysaccharides, there is no variation in structure among strains or even species, and all ECA molecules are composed of polysaccharides of N-acetylaminomannuronic acid, N-acetylfucosamine, and N,O-diacetylglucosamine. In the common form of this component, the polysaccharide is anchored to the outer membrane through a covalent linkage to phosphatidic acid.

The inner leaflet of the outer membrane bilayer is composed of the common glycerophospholipids. However, the quantitative composition is different from that found in the inner membrane. Phosphatidylethanolamine occupies over 90% of the glycerophospholipids in the outer membrane of *Salmonella*.

Proteins

The outer membrane is high in its protein content. Several different classes of proteins are found.

Structural proteins

There is a need to anchor the outer membrane to the underlying peptidoglycan for stabilization (Fig. 4). In enteric bacteria, this function is mainly carried out by the murein lipoprotein (or Braun lipoprotein), which is a small periplasmic protein (7200 daltons) with a covalently linked lipid moiety (a diglyceride and a fatty acyl residue are connected to the sulfhydryl group and the

Fig. 4 Anchoring of outer membrane to the peptidoglycan layer.

amino group, respectively, of the N-terminal cysteine). This protein connects the two structures by becoming covalently linked to peptidoglycan at its C-terminus, and non-covalently linked to the outer membrane bilayer through its lipid extensions at its N-terminus.

In *Pseudomonas aeruginosa* and related bacteria, murein lipoprotein is absent. Instead, the outer membrane is connected to the peptidoglycan by OprF and its homologs. OprF is a homolog of *E. coli* OmpA, and most of this protein folds into a two-domain conformer, with its N-terminal 8-stranded β -barrel buried in the outer membrane, at the same time its C-terminal periplasmic domain non-covalently associating with the peptidoglycan (Fig. 4).

Porins

Bacterial cells must take up nutrients from the environment, in spite of the presence of the outer membrane permeability barrier. For this purpose, all gram-negative bacteria apparently synthesize a special class of outer membrane protein called porins, whose narrow internal channel allows the diffusion of only small, hydrophilic nutrients. In *E. coli*, porins, which are present in about 10^5 copies per cell, are the most abundant protein in the cell, in terms of mass. *E. coli* porin channel has a dimension of 0.7×1.0 nm at its narrowest point, and disaccharides barely pass through this channel. Larger compounds (as a rough yardstick larger than about 600 daltons) are essentially excluded. Interestingly, lipophilic molecules are strongly retarded in their passage through this channel; this is apparently because at the narrowest point of the channel (the “eyelet”) the presence of acidic and basic amino acid residues on opposing walls (Fig. 5) creates a layer of highly ordered water molecules and passage of lipophilic solutes through this layer is energetically unfavorable as it has to disrupt this structure. Finally, *E. coli* porins favor the passage of cations over anions. It should be noted that these properties of the porin channels serve to prevent the entry of many toxic compounds, for example conjugated bile salts (lipophilic and anionic), perhaps the most important such compound for *E. coli* living in the intestinal tract of higher animals.

E. coli porins are trimers, each of which is composed of 16-stranded β -barrels (Fig. 5). *E. coli* produces three porins, OmpF, OmpC, and PhoE. Their structures are very similar to each other, yet there are subtle differences especially within the channel.

Fig. 5 X-ray crystal structure of *E. coli* OmpF porin. (A) View of the trimer from the top. Loop 2, colored blue, connects one protomer to the neighboring protomer. Loop 3, colored orange, folds back into the lumen of the β -barrel and narrows the diffusion channel. (B) View of the monomeric unit from the side. (C) View of the monomeric unit from the top, showing the “eyelet” or the constricted region of the channel. The eyelet is formed by acidic residues Glu117 and Asp113 from the Loop 3, and basic residues from the opposing barrel wall, Lys16, Arg42, Arg82, and Arg132, all shown in spherical models. This figure is from Nikaido, H., 2003. Molecular basis of bacterial outer membrane revisited. *Microbiol. Mol. Biol. Rev.* 67, 593–656.

In contrast to OmpF, PhoE favors the permeation of anions, and is expressed strongly under phosphorus starvation conditions presumably to enhance the uptake of phosphate and its esters from the environment. OmpC behaves as though its channel is slightly narrower than that of OmpF, and becomes a predominant porin when the ionic strength of the environment is close to, or over, that in the body fluids of higher animals. The predominance of OmpC in *E. coli* living in the intestinal tract will further enhance the exclusion of bile acids.

It should be emphasized that porins discriminate among various solutes on the basis of their global physicochemical properties, such as size, charge, and lipophilicity, and in this sense they show no specificity based on the exact fit between the protein and the ligand. Thus PhoE, for example, favors the diffusion of any anions, for example sulfate or anionic antibiotics, although such a behavior is not beneficial for the *E. coli* cells starved for phosphorus.

In recent years, electrophysiologists found that some antibiotics bind transiently to internal sites in porin channel, and proposals were made that one can calculate the diffusion rates of drugs from the kinetics of this binding. However, such an approach is flawed, because those drugs that show no tendency for binding do diffuse through porin channels quite rapidly. This “binding” (with a very low affinity) is evidently a laboratory artefact created by the very high resolution of modern electrophysiology.

Although trimeric porins are found universally in enteric bacteria, they are often absent in other groups of gram-negative bacteria. For example, *P. aeruginosa* and its relatives produce very impermeable outer membranes: they do not contain close homologs of OmpF/OmpC/PhoE, and the rate of penetration of hydrophilic solutes (such as cephalosporins) is almost two orders of magnitude slower than across the *E. coli* outer membrane. The major non-specific porin of these species is OprF, which is a homolog of *E. coli* OmpA and similarly acts as a structural protein anchoring the outer membrane to the peptidoglycan. The rate of penetration of solutes through the OprF channel is indeed nearly two orders of magnitude slower than through the OmpF channel, and this is explained by the fact that only a few percent of OprF protein folds to produce an open channel, although the channel itself is not narrow with an estimated diameter of about 2.0 nm.

Specific channels

It would be beneficial for *E. coli* to take up rapidly some solutes that are retarded or excluded by the trimeric porins. For *P. aeruginosa* with its inefficient general purpose porins, the need is acute to take up various types of nutrients more efficiently. For these purposes, many gram-negative bacteria produce specific diffusion channels. Since starch (amylose) is broken down to oligosaccharides of maltose series by pancreatic amylase in our intestinal tract, *E. coli* must take up these compounds efficiently, and for this purpose uses the LamB (lambda B, so named because it is used as the receptor by the *E. coli* bacteriophage lambda) channel, which served as a prototype of these specific channels.

LamB is also a trimeric protein composed of β -barrels. The barrel is slightly larger than in the porin, containing 18 strands in contrast to 16 in the OmpF homologs. However, the channel is narrower. The interior of the channel is exquisitely constructed to facilitate the passage of maltose oligosaccharides, with the succession of six aromatic amino acid residues constituting a “greasy slide” on which the sugars can slide past (Fig. 6). The channel has affinity to maltose and other higher oligosaccharides of this series,

Fig. 6 X-ray crystallographic structure of a specific channel, *E. coli* LamB. (A) Side view of the monomeric unit composed of 18-stranded β -barrel. Loop 3 (orange) and loop 1 (red) between the transmembrane β -strands (shown as flat arrows) fold back deeply into the central channel of the β -barrel, and makes the channel narrower. Loop 2 (blue) folds outward and interacts with other protomers of the trimeric structure. (B) View of the monomeric unit from the top. The residues of the greasy slide (Tyr41, Tyr6, Trp420, Trp358, and Phe227) are shown as blue stick diagrams, and Tyr118, which constricts the channel from the other side, is shown as a yellow stick diagram. (C) View of the greasy slide and its interaction with maltotriose. This is a side view, with the front of the β -barrel cut out for a better view of the slide. The aromatic residues comprising the helically twisted slide and Tyr118 are shown as stick diagrams, colored as in panel B. The maltotriose molecule (Triose) is shown as a stick diagram colored in orange. The diagrams are based on PDB coordinate files 1MAL and 1MPN, and produced with PyMol. This figure is from Nikaido, H., 2003. Molecular basis of bacterial outer membrane revisited. Microbiol. Mol. Biol. Rev. 67, 593–656.

and this serves to accelerate the transmembrane diffusion of these sugars (up to maltohexaose, 990 daltons) when they are present in low concentrations. When they are present in nonphysiological, high concentrations, smaller oligosaccharides such as maltose can diffuse through the nonspecific porin channels as well, or even faster.

There are several other specific *E. coli* channels that have been studied in detail. These include the channels for sucrose (ScrY), arylglucosides (BglH), nucleosides (Tsx), and fatty acids (FadL). In *P. aeruginosa*, the channel protein OprD was studied because it plays a major role in the rapid influx of imipenem, an antibiotic that shows an exceptional activity against this organism, and appears to be a specific channel for basic amino acids and peptides. Interestingly, *P. aeruginosa* contains 19 homologs of this protein; probably each of these produces a specific diffusion channel for a specific type of nutrients needed by this organism, whose general-purpose porin, OprF, is very inefficient as described above.

TonB-dependent receptors

Gram-negative bacteria need to take up some large compounds that exist in extremely low concentrations in the environment. These include the iron-siderophore complexes for the uptake of iron, and vitamin B₁₂. *E. coli* for example produces specific outer membrane transporters for ferric enterobactin (726 daltons, the chelator produced by *E. coli* itself) (FepA), for ferrichrome (chelator produced mostly by fungus) (FhuA), for coprogen (FhuE), for ferric citrate (FecA), for dihydroxybenzoate-ferric complex (Fiu), for ferric complexes of similar catecholate-type compounds (Cir), and for vitamin B₁₂ (1355 daltons) (BtuB). For the uptake of these compounds, even specific channels are not adequate, because diffusion through these channels is driven ultimately by the difference in concentrations across the membrane, which is vanishingly small for these compounds. They are, therefore, transported across the outer membrane by an active process, with the concomitant consumption of energy. Since there is no ATP in the periplasm or the outer membrane, the energy coupling is done by an ingenious process of using a periplasmic protein, TonB, to transduce the energy from the cytoplasmic membrane, as discussed in Section “Functional Complexes Involving Multiple Components of the Cell Envelope”.

The outer membrane proteins involved are usually called receptors, because they show very strong affinity to the transported ligands, with the dissociation constants in the range of nanomolar. Since the ligands are present in such low concentrations, this high affinity is absolutely needed. X-ray crystallographic studies showed that the proteins have the basic construction of a β -barrel, with 22 transmembrane β -strands (Fig. 7). The proteins appear to exist as monomers, in contrast to the OmpF-type porin and the LamB protein. Furthermore, a large N-terminal portion is folded into the barrel, as though to “plug” the large central channel inside the β -barrel. Recent years have seen impressive progress in our understanding of the interaction between TonB and these receptors (see below), but we still do not know how the active transport of the ligands is achieved.

Fig. 7 X-ray crystallographic structure of the ferric citrate receptor, FecA. (A) Side view of the unliganded FecA. The N-terminal domain of this protein is inserted into the lumen of the large, 22-stranded β -barrel (green) as a “plug” (orange). Its N-terminal end contains the “TonB box” sequence, predicted, and now shown, to interact with the C-terminal part of the TonB protein. Loops 7 and 8 are shown in deep blue and mauve, respectively. (B) Liganded FecA. Binding of ferric citrate (shown with two large blue spheres indicating iron atoms and with stick models for citrate) produces movement of loops 7 and 8. The TonB box also becomes disordered and invisible. Based on PDB files 1KMO and 1KMP. This figure is from Nikaido, H., 2003. Molecular basis of bacterial outer membrane revisited. Microbiol. Mol. Biol. Rev. 67, 593–656.

Export channels

E. coli TolC is an outer membrane protein that exists as a symmetrical trimer. The trimer contains the 12-stranded β -barrel that functions as a channel traversing the outer membrane, but in this case each monomer contributes only four of the 12 transmembrane strands. Remarkably, the channel extends about 10 nm into the periplasm, this time as a bundle of 12 long α -helices. This arrangement allows the end of the periplasmic α -tunnel to become connected to the external end of the transporters in the inner membrane, producing a direct extrusion mechanism for substrates into the medium, bypassing the periplasm. Thus TolC and its homologs are essential components for some of the machineries that export proteins and drugs (see below).

A very different arrangement is also used in the export of various proteins into the medium. Here a rather large number (12–14) of intrinsic outer membrane proteins assemble to produce a large channel. This occurs in the type II secretion pathway, discussed below, and the protein here is called secretins. Similar large channels are also envisaged for the pathway leading to the export of P pili subunits, and here the proteins are called ushers.

Biosynthesis and Assembly of Outer Membrane Components

Biosynthesis of Component Macromolecules

The synthesis of macromolecules (LPS, outer membrane proteins) obviously takes place in the cytosol where ATP and other sources of energy are available. The biosynthesis of LPS is now understood in details. The synthesis of lipid A starts from an activated form of N-acetylglucosamine, UDP-N-acetylglucosamine (Fig. 8). In the first reaction, a C14 hydroxylated saturated fatty acid (3-OH myristic acid) residue is added to the 3-position of the sugar (step 1 in Fig. 8), followed by the deacetylation (step 2) and further addition of another 3-OH myristic acid residue on the now-deacetylated 2-amino group on the sugar (step 3). Two of these diacylated molecules are fused together, to produce a 1-phosphorylated tetraacylated disaccharide (step 4), which is then phosphorylated at the other end of the disaccharide (step 5), to produce a structure commonly called Lipid IV_A, which shows significant endotoxic activity. Just like the acylation reactions preceded the formation of disaccharide, the addition of the innermost sugar residues, two Kdo (ketodeoxyoctonate, or 3-deoxy-D-mannooctulosonic acid) residues of the core portion are added next (step 6), before the addition of two other fatty acid residues to complete the acylation reactions (steps 7 and 8).

The product of the series of reactions described above, (Kdo)₂-lipid A, then accepts various sugars of the core domain (Fig. 3) from nucleoside-sugar donor molecules. Since these nucleoside-sugars are components of the cytosol, these transfer reactions must occur at the inner surface of the cytoplasmic membrane. The final product of the synthesis up to this point, the complete R LPS (see glossary), is flipped across the cytoplasmic membrane by an ABC (ATP-binding cassette) transporter MsbA.

The biosynthesis of the outer part of the LPS polysaccharide, O chain, proceeds separately from that of the R LPS. Many O chains are composed of branched oligosaccharide repeat units, and such a unit is assembled again at the inner surface of the cytoplasmic membrane, by using nucleoside-sugar molecules as donors, on a large (C55) isoprenoid lipid carrier, undecaprenol phosphate,

Fig. 8 Pathway of lipid A biosynthesis in *E. coli*. Note that acylation of the sugar occurs before the formation of the disaccharide head group, and that addition of two Kdo residues occurs before the completion of all acylation reactions. Thus the final product is (Kdo)₂-lipid A, and is not lipid A (which was defined as a product of partial acid hydrolysis of LPS). In other species of gram-negative bacteria, the acylation pattern of lipid A may be different from what is shown here.

bound non-covalently to the membrane. When the repeating unit assembly is complete, the oligosaccharide-lipid complex is apparently flipped over across the membrane by a transporter called Wzx. At the outer surface of the membrane, the repeating units are polymerized by an enzyme Wzy, and the completed O chain is finally transferred, at the periplasmic surface of the cytoplasmic membrane, to the nascent R LPS.

Some unbranched O chains of rather simpler structure are assembled again on the inner surface of the cytoplasmic membrane. However, in this case, the completely assembled, long, O chain is extruded by an ABC transporter across the cytoplasmic membrane, before its transfer to the R LPS presumably at the outer surface of the cytoplasmic membrane.

Outer membrane proteins are synthesized by ribosomes in the cytosol. They are then exported across the cytoplasmic membrane, apparently always utilizing the SecYEG pathway. How these proteins become assembled into the outer membrane is described in the next section.

Assembly

The components of the outer membrane, after their export across the cytoplasmic membrane, somehow travel across the periplasm, and are finally assembled in the outer membrane. After the export across the cytoplasmic membrane, all the processes must proceed without utilizing ATP. Some of the mechanisms involved are becoming elucidated in the last several years.

Assembly of outer membrane proteins

The export of lipoproteins is understood in most detail. After the apoprotein is exported in the unfolded state by the SecYEG machinery, the lipids are added. Since this is done on the periplasmic surface of the cytoplasmic membrane, where no ATP is available, the transfer is done by utilizing membrane phospholipids as donors. It was known for some time that some lipoproteins associate themselves with the inner leaflet of the outer membrane, while others remain anchored to the outer leaflet of the inner membrane, and furthermore that the fate of the lipoproteins is dependent on the nature of the second amino acid residue from the N-terminus after the cleavage of the leader sequence. If this residue is aspartate, the protein is retained in the inner membrane, and if it is a neutral residue such as serine, the protein is exported to the outer membrane.

Recent studies elucidated the molecular mechanism of this differential export process for lipoproteins. Thus lipoproteins become the substrates of an unusual ABC transporter, LolCDE, whose function is to “transport” them (with the utilization of ATP at the inner surface of the cytoplasmic membrane) to a periplasmic binding protein, LolA (Fig. 9). LolA-lipoprotein complex then reacts with the LolB protein, located at the inner surface of the membrane, and the lipoprotein is now delivered into the inner leaflet of the outer membrane. Those lipoproteins with aspartate as the second amino acid will escape the recognition by the LolCDE complex, and will thus remain anchored in the cytoplasmic membrane.

We have also gained much understanding on the mechanism of assembly of the integral outer membrane proteins. Unlike lipoproteins, which are inserted into the outer membrane only through their lipid groups, most integral outer membrane proteins traverse both leaflets of the membrane, and characteristically are composed of β -barrels. Since most intrinsic proteins of the cytoplasmic membrane are bundles of transmembrane α -helices, the unusual β -barrel conformation of the outer membrane proteins certainly suggests a unique mechanism of export and assembly for these proteins. An outer membrane protein, called

Fig. 9 Mechanism of lipoprotein export. After export through the SecYEG exporter, the signal sequence is cleaved, to expose the N-terminal cysteine of the mature protein. This residue is lipid-modified, and the lipoprotein interacts with the LolCED ABC transporter, with its ATPase units (LolD) (step 1). If the second amino acid residue is Asp, it is an inner membrane lipoprotein, and is released and stays in the inner membrane (step 1A). If it is a neutral amino acid, then the lipoprotein is actively transferred to a periplasmic binding protein, LolA (step 2), and finally interacts with the outer membrane receptor protein LolB (which itself is a lipoprotein), to be assembled into the inner leaflet of the outer membrane (step 3).

Fig. 10 BamA and associated proteins play a major role in the insertion of β -barrel proteins into outer membrane. (A) X-ray crystal structure of BamA-BamB-BamC-BamD-BamE complex. (B) Close-up of BamA β -barrel domain. (C) The first several β -strands of the barrel become reoriented upon binding of BamCDE to BamA, creating a lateral opening between $\beta 1$ and $\beta 16$. These figures are from Bakelar, J., Buchanan, S.K., Noinaj, N., 2016. The structure of the β -barrel assembly machinery complex. *Science* 351, 180–186.

Omp85 (or BamA), is at the center of this assembly process. In a cell depleted for BamA, outer membrane proteins accumulate in an unfolded form, and are not assembled into the outer membrane. BamA is also a β -barrel, but it has a long N-terminal extension, containing five repeated POTRA (polypeptide-transport-associated) domains that exist in the periplasm. The POTRA domains interact with four lipoproteins (BamB, BamC, BamD, and BamE) (Fig. 10(A)). It seems likely that new outer membrane proteins, exported into periplasm, become associated, in their unfolded state, with periplasmic chaperones such as SurA (a periplasmic chaperone that also has an activity in catalyzing the *cis-trans* interconversion of peptidyl-proline isomers) or Skp, and eventually enter the large cavity of BamA barrel. It is still unclear if the folding of the substrate protein into β -barrel mainly takes place during its association with POTRA domains, or within the central cavity of BamA barrel. However, it appears that the first several strands of BamA barrel undergo an unusually large reorientation upon the binding of BamCDE, so that a lateral opening is created for the export of folded substrate proteins into the outer membrane (Compare Fig. 10(C) with (B)). The presence of BamA homologs in the outer membranes of chloroplasts and mitochondria and their apparent role in the assembly of proteins in these plastid outer membranes support the important role for this protein.

The process of export and assembly of outer membrane proteins is thus complex, and errors are likely to occur at every step of the pathway. Thus the periplasm has a highly evolved mechanism for sensing such errors, and for correcting them (see Section “Periplasm” below).

Assembly of LPS

We have described how the complete LPS is assembled on the outer (periplasmic) surface of the cytoplasmic membrane. LPS, however, has still to cross the periplasm, become inserted into the outer membrane, and most importantly in the outer leaflet of this membrane. How this complex series of reactions takes place has been elucidated in recent years. An outer membrane protein, earlier called Imp (for increased membrane permeability), was known as an essential protein in *E. coli*, and its mutated version was known to produce *E. coli* cells with a “leaky” outer membrane. LPS is also essential for the survival of *E. coli*. In contrast, another species of gram-negative bacteria, *Neisseria meningitidis*, can survive without LPS. Imp is also not essential in this organism.

Fig. 11 Pathway of export of LPS to the outer membrane. (A) A schematic showing the pathway through Lpt proteins. A through G refer to LptA through LptG. Most likely more than one copy of LptA is involved in the transport, but only one copy is shown here for clarity. From Okuda, S., Sherman, D.J., Silhavy, T.J., Ruiz, N., Kahne, D., 2016. Lipopolysaccharide transport and assembly at the outer membrane: The PEZ model. *Nat. Rev. Microbiol.* 14, 337–345. (B) X-ray crystal structure of LptD. The external ring of aromatic amino acids that are characteristically located at the membrane-solvent boundary region is indicated in orange. The short and disordered $\beta 1$ through $\beta 3$ strands create crenellation in the β -barrel, through which LPS is thought to be moved directly into the outer leaflet of the outer membrane. From Qiao, S., Luo, Q., Zhao, Y., Zhang, X.C., Huang, Y., 2014. Structural basis for lipopolysaccharide insertion in the bacterial outer membrane. *Nature* 511 (7507), 108–111. <http://dx.doi.org/10.1038/nature13484>.

Inactivation of the *imp* gene in this organism showed that none of the newly synthesized lipopolysaccharide appeared on the cell surface, that is, in the outer leaflet of the outer membrane, suggesting the role of Imp in the correct assembly of lipopolysaccharide in its proper location.

Imp, now renamed Lpt(lipopolysaccharide transport)D, forms a huge β -barrel with 26 strands. In order to prevent the massive influx of large molecules from outside, it is plugged most of the time by LptE (see Fig. 11). LptD is the terminus of a long export route that is energized by an ABC transporter LptFGB₂ (Fig. 11(A)). ATP hydrolysis by this engine first drives newly assembled LPS to the inner membrane protein LptC. LptC, a few copies of periplasmic carrier LptA, and the periplasmic extension of LptD form a continuous structure that spans the thickness of periplasm (Fig. 11(A)). Moving newly made LPS along this export pathway (as in the delivery machine for PEZ candy) is the function of successive hydrolysis of ATP at the ABC transporter. Finally, once in the lumen of the LptD β -barrel, LPS is thought to be delivered laterally directly to the outer leaflet of the outer membrane, as the β -barrel here is crenellated with shorter and more unstable β -strands where the $\beta 3$ -to- $\beta 1$ strands interact with the $\beta 26$ strand (Fig. 11(B)).

Assembly of phospholipids

Phospholipids are synthesized in the inner leaflet of the inner membrane, and thus the first step for its export might be the flipping to the outer leaflet. Although MsbA was suggested to catalyze this reaction, in *Neisseria msbA* null mutants export and assemble phospholipids into the outer membrane, and thus MsbA cannot be essential for phospholipid export. Currently there is little information on the export pathway of phospholipids, which were shown to equilibrate rapidly between the outer and inner membranes. (Recently, a cardiolipin exporter PbgA was identified in *Salmonella*, although this system becomes activated only in animal tissues).

However, phospholipid molecules are expected to reach slowly the outer leaflet of the outer membrane, most likely through the spontaneous flipping process. This will destroy the permeation barrier that is dependent on the asymmetric construction of the outer membrane. Thus cells try to remove these phospholipid molecules from the outer leaflet. One mechanism is their hydrolysis by the outer membrane phospholipase OmpLA. The second mechanism is the use of outer leaflet phospholipid as the donor of acyl group to LPS, via the transferase PagP. The third system, Mla (maintenance of lipid asymmetry) resembles the Lol system (Fig. 9), and contains an outer membrane lipoprotein, a periplasmic protein, a putative binding protein associated with the inner membrane, as well as an ABC transporter that presumably energizes the active backward transport of phospholipids from the outer leaflet of the outer membrane all the way into the inner membrane. Interestingly, the inner-membrane-associated binding protein MlaD belongs to MCE family of proteins, known to be involved in the import of hydrophobic molecules, such as steroids, in mycobacteria.

Periplasm

The space between the outer and inner membranes contains the periplasm. This is not just an empty “space”, and it contains many distinct components that carry out important functions. Obviously, this space contains peptidoglycan, but hints of its unique

function came from the discovery that several degradative enzymes of *E. coli*, for example ribonuclease and alkaline phosphatase, are found exclusively in the periplasm. Since these enzymes will destroy essential components of the cytosol if they existed in the cytoplasm, their compartmentalization within the periplasm, outside the cytosol, makes sense in terms of physiology.

One analysis on the basis of genome sequence of *E. coli* predicts about 370 periplasmic proteins, in comparison with only about 150 proteins to be located in the outer membrane. Another large class of periplasmic proteins includes ligand-binding proteins that form a part of the ABC (ATP-Binding Cassette) transporters, that import many compounds, including sugars, amino acids, peptides, inorganic ions such as phosphate and sulfate as well as metal cations, ferric-siderophore complexes, vitamin B12, and others. Another class includes proteins involved in electron transport. Now it is known that enzymes like formic hydrogenlyase and aerobic nitrate reductase, with their molybdate factor, are components of the periplasm. Although *E. coli* lacks the typical cytochrome *c* found in the corresponding space in mitochondria, there are several *c*-type cytochromes that function in the reduction of alternate electron acceptors. Yet other important class includes enzymes involved in peptidoglycan biosynthesis. β -Lactamase, which was apparently derived from one of these enzymes during evolution, plays a predominant role in raising the intrinsic level of resistance of gram-negative bacteria to penicillins and cephalosporins, the most important class of antimicrobial compounds. Finally, periplasm contains many proteins that assist in the folding of periplasmic and outer membrane proteins. These include proteins involved in the formation of disulfide bonds, such as DsbA, DsbB, DsbC, and others. The cytoplasm of gram-negative bacteria is a highly reducing environment, which contains hardly any disulfide-bond-containing proteins. In contrast, disulfide bonds are found commonly in periplasmic and outer membrane proteins, and their formation presumably helps in the folding of these proteins after their export, in an unfolded form, through the SecYEG export apparatus across the cytoplasmic membrane. Periplasm also contains many proteins that appear to function as molecular chaperones including Skp and SurA that have already been mentioned.

In addition, it is essential to have an intricate regulatory mechanism that senses the proper functioning of the protein folding and transport machinery. Periplasm in fact contains at least two major such signal transduction pathways. One of them, sigma E pathway, becomes activated when periplasmic or outer membrane proteins misfold at high temperature or under other conditions, and the activation of the alternative sigma factor E increases the transcription of many dozens of genes, many related to the folding of proteins in the periplasm, such as SurA, Skp, DsbC, and another peptidyl-prolyl isomerase, FkpA. At the same time, the synthesis of periplasmic proteases, such as DegP, is increased strongly, presumably to degrade misfolded proteins. The response also increases the transcription of many genes involved in lipid A synthesis, as well as the genes for the assembly of outer membrane proteins and lipopolysaccharides. The transcription of some outer membrane protein genes is on the other hand strongly repressed (*ompA* and *lamB* via small RNA *micA*; *ompC* and *ompX* via *rybB*). The sigma factor works with the core RNA polymerase in the cytosol, yet it has to be activated by signals in the periplasm. The mechanism is detailed in Fig. 12.

Fig. 12 Envelope stress responses. In σ^E response, the misfolded proteins in the periplasm binds to protease DegS and activates it. The periplasmic portion of the transmembrane protein RseA is normally protected by the bound RseB, but the latter becomes displaced by truncated LPS in the periplasm. The periplasmic and intramembranous portions of RseA are then degraded by DegS and RseP proteases, and the cytosolic portion of RseA is degraded mainly by ClpXP, finally releasing the alternative sigma factor σ^E . In the Cpx pathway, the sensory histidine kinase CpxA is activated by diverse conditions, leading to the phosphorylation of the response regulator CpxR, which also leads to the activation of the σ^E pathway. From Grabowicz, M., Silhavy, T.J., 2017. Envelope stress responses: An interconnected safety net. Trends Biochem. Sci. 43, 232–242.

The second signal transduction pathway, CpxAR, is a typical two-component system that uses an intrinsic inner membrane protein CpxA to sense the extracytosolic signal. It responds to the presence of misfolded proteins in the periplasm and the inner membrane (presumably caused by conditions like high pH, high salt concentration, and altered inner membrane lipid composition). It is also stimulated by the attachment of *E. coli* cells to a hydrophobic surface, via the outer membrane lipoprotein NlpE (Fig. 12). The activation of Cpx system stimulates the production of its own periplasmic inhibitor CpxP, preventing the runaway response. It also prevents the synthesis of OmpF and other outer membrane proteins through small RNA *micF*. There is also an interaction with the sigma E pathway.

The general physical environment of the periplasm requires some comment. It was shown by Stock et al. (1977) that the periplasm is in osmotic equilibrium with the cytosol. Cytosol is usually kept at a hyperosmotic state in comparison with the medium, so that the cytosol will not collapse and a moderate outward pressure is constantly present at the cytoplasmic membrane in a “balloon-in-a-cage” arrangement limited by the mechanically strong peptidoglycan. How then could the periplasm remain hyperosmotic in relation to the medium, in the presence of so many porin channels? Stock and coworkers found that interior-negative Donnan potential exists across the outer membrane, and that this results in the passive accumulation of cations in periplasm. Later studies led to the identification of the cause of this Donnan potential, the presence in the periplasm of “membrane-derived oligosaccharides” (MDO), a group of glucose oligosaccharides too large to escape through the porin channels and containing multiple negative charges. MDO is produced in large amounts when the osmotic activity of the medium is low, so that many cations can be concentrated in the periplasm. Protons, as cations, are also concentrated in the periplasm. Thus depending on the conditions, the periplasmic pH can be significantly lower than that of the medium, a fact that is not generally appreciated. The Donnan potential also affects the uptake of drugs across the outer membrane, favoring that of cationic drugs (especially polycationic ones such as aminoglycosides) and preventing to some extent the uptake of anionic compounds.

Functional Complexes Involving Multiple Components of the Cell Envelope

In the late 1960s, Manfred Bayer found by electron microscopy structures that seemed to connect the outer membrane with the inner membrane. This discovery was greeted with skepticism at that time, but recent genetic and biochemical studies showed many instances where physical interaction must occur between the components of the two membranes.

A prominent example is the bacterial flagella, whose “basal body” traverses the cytoplasmic membrane, peptidoglycan, and the outer membrane; we will not discuss flagella in detail, because this organelle is described in other chapters of this encyclopedia.

Another example of trans-envelope machinery contains the outer membrane receptors for iron-siderophore complexes and vitamin B₁₂. Bacteria need iron as a component of many enzymes and respiratory complexes. But the ferric ion found in aerobic environment occurs at an exceedingly low concentration because of its low solubility. Thus bacteria produce siderophores, or iron carriers, that bind the ferric ion strongly and move them into the cytoplasm. However, both iron-siderophore complexes (726 daltons for ferric enterobactin) and vitamin B₁₂ (1355 daltons) are too large to pass through the porin channels of enteric bacteria. Thus these bacteria produce specific outer membrane receptor proteins that bind these compounds strongly; these receptors contain a large, 22-stranded β -barrel, which is occluded by an N-terminal “plug” domain. Transport of these substrates into the periplasm requires TonB, a periplasmic, elongated protein that is embedded in the cytoplasmic membrane at one end and appears to traverse the thickness of the entire periplasm, to interact with the outer membrane receptors. Near the N-terminus of the plug domain, there is a small structure called TonB box. The C-terminal domain of TonB apparently interacts strongly with the TonB box, by supplying one of the strands to complete a β -sheet structure. This process thus involves physical connection between the inner and outer membranes (Fig. 13). TonB-dependent transport requires proton-motive force and the inner-membrane-embedded proteins ExbB

Fig. 13 Hypothetical model of TonB-dependent transport complex. TonB appears to have an N-terminal transmembrane helix, which may interact with at least two other intrinsic inner membrane proteins, ExbB and ExbD, needed for energy transduction. The other end of TonB has been hypothesized to interact with the TonB box of various receptors, and indeed cocrystals of receptors with TonB showed that this physical interaction occurs.

and ExbD. These latter proteins are homologous to the stator of flagellar motor, and proton-motive force was shown to result in the rotation of TonB protein, which presumably helps in locating the outer-membrane-embedded transporters and in facilitating the interaction of its C-terminal domain with the TonB Box.

Another example is a group of multidrug efflux pumps in gram-negative bacteria. These bacteria were found, since the mid-1990s, to pump out great many antibiotics and chemotherapeutic agents, often utilizing transporters of an astonishing degree of versatility. One class, called RND (resistance-nodulation-division) superfamily, is particularly important. They are ubiquitous and often show an extremely wide range of substrate specificity. For example, AcrB (so named for acridine resistance) pump of *E. coli*, which served as the prototype of these transporters, can pump out not only most of the commonly used antibacterials (including penicillins, cephalosporins, macrolides, rifampicin, fluoroquinolones), dyes, antiseptics, and detergents, but also even simple solvents. Furthermore, RND pumps are organized into multi-protein complexes that span both the inner and outer membranes (Fig. 14), together with an outer membrane channel (TolC in *E. coli*) and a periplasmic linker protein. This construction allows the complex to move drug molecules directly into the medium, a mechanism that is very advantageous in gram-negative bacteria. A simple, uncomplexed pump located in the inner membrane would only move drugs from the cytosol to the periplasm, and the drug molecules can diffuse into the cytosol spontaneously and rather easily, as drugs with cytosolic targets must have rather lipophilic structures to allow this influx process (Fig. 14). In contrast, the tripartite, cell-envelope-spanning structures of the RND pumps causes the movement of drugs from the periplasm into the external medium; thus the extruded drug molecule has to traverse the effective outer membrane barrier again, in order to come into the cell. It is well known that most of the naturally occurring antibiotics (for example penicillin G and erythromycin) and of the library of chemically synthesized antibacterial compounds (for example linezolid) exhibit activity only against gram-positive bacteria. This “intrinsic” resistance of gram-negative bacteria was often attributed to the barrier properties of the outer membrane. However, in many cases the inhibitors are actively pumped out by these ubiquitous multidrug efflux pumps, and the contribution of the pumps is at least as important as that of the outer membrane barrier.

Final examples of the structures spanning both membranes are machineries dedicated for extracellular secretion of proteins and other macromolecules. With gram-positive bacteria, protein secretion is only a matter of moving the protein across the cytoplasmic membrane. In contrast, with gram-negative bacteria, it becomes necessary to prevent the premature folding of the protein in the periplasm, and to push the protein through another membrane barrier, the outer membrane. Yet most bacteria, especially pathogens, have a need to secrete toxic proteins into the external space, and in some cases even into the host cells, a process requiring the breaching of yet another membrane barrier.

Several mechanisms have been devised for protein secretion in gram-negative bacteria (Fig. 15). As seen, most of these machineries involve protein assemblies that traverse the entire cell envelope, although there exist a few systems that are confined in the outer membrane (Type 5 secretion system that is autotransporter, chaperone-usher pathway used in the secretion of fimbriae subunits, and curli biogenesis system). In the simplest system, the type I secretion pathway, the proteins are pushed out across the

Fig. 14 AcrB-AcrA-TolC as an example of RND-type efflux pump complex. (A) A crude schematic depiction of the complex. Amphiphilic drugs slowly penetrate across the outer membrane, either through the porin channel or through the asymmetric bilayer, and upon reaching the periplasm are likely to become captured by the periplasmic domain of the transporter, to be expelled directly into the medium. (B) Cryo-EM structure of the entire complex (from Wang, Z., Fan, G., Hryc, C.F., *et al.*, 2017. An allosteric transport mechanism for the AcrAB-TolC multidrug efflux pump. *eLife* 29 (6), e24905. <http://dx.doi.org/10.7554/eLife.24905>). Component proteins are colored differently (TolC in red and pink; AcrA in orange and green, AcrB in blue, and AcrZ in purple). AcrZ is a recently discovered component that enhances the activity of this pump complex.

Fig. 15 Machineries for protein export in gram-negative bacteria. The figure shows the construction of protein secretion apparatus spanning the entire cell envelope, in a schematic manner. For the type 3 system, nomenclature for the *S. typhimurium* system is shown. The type 4 system shown is based on the nomenclature of the VirB/D system in *Agrobacterium tumefaciens*. The type 6 system nomenclature is those from enteroaggregative *E. coli* and *Vibrio cholerae*. This figure is from Costa, T.R.D., Felisberto-Rodrigues, C., Meir, A., *et al.*, 2015. Secretion systems in gram-negative bacteria: Structural and mechanistic insights. Nat. Rev. Microbiol. 13, 343–359.

cytoplasmic membrane by a transporter, a member of the ABC (ATP-Binding Cassette) superfamily. Although ABC transporters catalyze the active transport (both import and export) of a variety of substrates, both small and large, this system is unusual in the sense that the transporter exists as a multi-protein complex including the outer membrane channel protein TolC and a periplasmic linker protein, so that the exported protein can cross the entire cell envelope, without facing the aqueous environment of the periplasm. The system shown is utilized in the secretion, by *E. coli*, of hemolysin, a toxin. (An ABC system exporting drugs, MacAB, is coupled also to TolC using the periplasmic accessory protein MacA).

In the Type II secretion system (Fig. 15), the exported proteins include enzymes, such as pullulanase of *Klebsiella pneumoniae*. The substrate is exported across the cytoplasmic membrane usually by the SecYEG complex, but export across the outer membrane requires a complex machinery traversing both membranes, and is energized by a cytoplasmic ATPase GspE. Although the detailed mechanism is not yet clear, the overproduction of the major pseudopilin GspG (so called because of its homology to a class of pilins) in *E. coli* produces pili on the cell surface. Thus it is thought that the hydrolysis of ATP by GspE results in the polymerization of GspG (in a way similar to the polymerization of pilin by ATP hydrolysis), which produces a piston-like structure in the cavity, which would push the substrate protein through the outer membrane channel of GspD.

In the Type III secretion system (Fig. 15) again a complex assembly of many proteins are required. This system usually has a long, needle-like extension outside, and is often thought to “inject” proteins into the cytosol of the host cells. Indeed the genes coding for this system are often found in the “pathogenicity islands” on the bacterial chromosome, where many genes involved in the infection process are clustered together. Another fascinating aspect of this system is that many of its proteins are similar to the components of the basal bodies of bacterial flagella, suggesting that flagella and this secretion system have a common evolutionary origin.

Type IV secretion system is also complex and contains many proteins (Fig. 15). A prototype of this system is the VirB system, shown in the figure, that is responsible for the export of a piece of single-stranded DNA (and associated proteins) from the bacterium *Agrobacterium tumefaciens* into plant cells. (This system was used in the production of most of the genetically modified crop plants.) Interestingly, a very similar system is involved in the conjugational transfer of plasmid DNA from one bacterial cell to another.

Type VI secretion system often participates in competition between different species of bacteria, by injecting a toxic protein into cells of the competing bacterial species. It is evolutionarily related to the contractile sheath-tube assembly of bacteriophage tail, and is thus thought to function in a similar way, by the tail contraction leading to the injection of the toxic protein labeled VgrG spike in Fig. 15. After injection, the machinery is thought to become disassembled by the ClpV ATPase.

Mycobacterial Cell Envelope

Although mycobacteria are not gram-negative, their lipid-rich cell envelope appears to have an overall structure similar to the gram-negative envelope. This was suggested by the observation that the hydrocarbon chains of the cell wall lipids are in a state of very low fluidity, and are arranged in a direction perpendicular to the plane of cell surface (Fig. 16). However, unlike in the outer membrane, in mycobacteria the least permeable portion of the cell envelope or the outer membrane appears to correspond to its inner part,

Fig. 16 A model of mycobacterial cell envelope, based on the quantitative analysis of outer and inner membrane lipids of *Mycobacterium smegmatis*. Reproduced from Bansal-Mutalik, R., Nikaido, H., 2014. Mycobacterial outer membrane is a lipid bilayer and the inner membrane is unusually rich in diacyl phosphatidylinositol dimannosides. *Proc. Nat. Acad. Sci. USA* 111, 4958–4963. The envelope contains four layers, i.e., OM (outer membrane), AG (arabinogalactan), PG (peptidoglycan), and IM, inner membrane. The inner leaflet of OM is composed of mycolic acid, a branched fatty acid with very long chains of uneven lengths (typically 24 and 60 carbons), covalently linked to AG, with its longer arm folded. The outer leaflet of OM is composed mostly of TAG (triacylglycerol), DAG (diacylglycerol), as well as GPL (glycopeptidolipid). IM is the conventional phospholipid (PL) bilayer, but we found that it contains a very high proportion of diacyl phosphatidylinositol dimannoside (Ac_2PIM_2), which was here assumed to comprise the entire inner leaflet. Since this phospholipid contains two additional fatty acid chains linked to the inositol and one of the mannose residues, it has four acyl chains linked to one head group, which may make mycobacterial IM bilayer less permeable than the usual phospholipid bilayer. IM contains also other (glycerol)phospholipids (PLs), diacyl phosphoinositol hexamannosides (Ac_2PIM_6), trehalose monomycolate (TMM), and apolar lipids.

where long, saturated hydrocarbon chains of mycolic acid residues are packed together. Indeed this portion of the cell wall seems to have a very low fluidity, and very low permeability for lipophilic molecules is expected for the mycobacterial cell wall. The mycobacterial cell envelope has an exceptionally low permeability also for hydrophilic solutes, even lower than the *P. aeruginosa* outer membrane in some species. Porins were identified in the envelope of fast-growing species such as *Mycobacterium smegmatis*, although they are very different proteins from gram-negative porins. The number and properties of these mycobacterial porins appear to explain the low permeability of the envelope.

Overview of Plant Diseases[☆]

R Kenneth Horst, Cornell University, Ithaca, NY, United States

© 2019 Elsevier Inc. All rights reserved.

Infectious diseases are caused by fungi, bacteria, viruses and nematodes. Fungi are organisms which have no chlorophyll, reproduce by sexual and asexual spores and typically possess mycelia or a mass of interwoven threads (hyphae). There are about 70,000 species living as parasites or saprophytes on other organisms or residues and more than 8000 species causing plant disease. The most serious and widespread fungal diseases of rose are powdery mildew caused by *Podosphaera pannosa* (Wallr.: Fr.) de Bary and black spot caused by *Diplocarpon rosae* Wolf.

Plant pathogenic bacteria are generally unicellular, nonspore-forming rods. There are about 80 species of bacteria which cause plant disease and many of them consist of numerous pathovars. The identification of bacteria can be very difficult; it involves special staining techniques, biochemical tests and serology. Pathogenic bacteria enter plants through insects or other wounds, through stomata, hydathodes, lenticels and flower nectaries. The most widespread bacterial disease of rose is crown gall caused by *Agrobacterium tumefaciens* (E. F. Sm. and Town.) Conn.

Viruses contain two major components: nucleic acid surrounded by a protein coat. There are over 850 described plant virus species. Some attack a large number of different plants and are of great economic importance: others are confined to a single host. Viruses are transmitted from plant to plant by insects, mites, fungi, nematodes, water, and by rubbing, abrasion or other mechanical means. Viruses are differentiated and identified by host specificity, physical properties, purification, electron microscopy, electrophoresis and serology. The most widespread viral disease of rose is rose mosaic. Rose mosaic is generally associated with isolates of *Prunus* necrotic ringspot virus (PNRSV) or with mixed infections with PNRSV, apple mosaic virus and *Arabis* mosaic virus.

Nematodes are unsegmented roundworms that inhabit fresh and salt water, decaying organic matter, soil, plants and animals throughout the world. More than 2000 species are parasitic on plants. Most plant nematodes are root parasites, but some live in stems, leaves or buds. Some cause galls and others produce general yellowing, stunting or dieback that is often ascribed to other causes such as nutrient imbalance.

Commercial production of plants free of disease requires frequent observations and intelligent strategic planning. Prevention is essential for good disease control. Although control can vary from partial to economic to perfect, the best disease control is when it is profitable to crop production. Even before the discovery of Bordeaux mixture, it was determined by trial and error that chemicals could be useful for pest control. For example, sulphur was known to avert pests by Homer in 1000 BC and was probably generally used by 1800. In 1824 Robertson recommended sulphur for control of powdery mildew of peach. Lime-sulphur found its way into disease control by 1906 and copper sulphate was recommended for roses in 1862.

These early observations and discoveries led to mixing lime and copper sulphate. This mixture was first used on grapes to deter pilfering in Médoc, France. However, Millardet in 1882 observed that the mixture (called Bordeaux mixture, after the location where it was first used) controlled the severe downy mildew disease of grapes. This discovery marked the true beginning of the modern era of chemicals to control plant disease. Bordeaux mixture is still used today; its greatest deterrent is a tendency to be phytotoxic. Sulphur, lime-sulphur and Bordeaux mixture were the major tools for disease control in ornamentals from 1900 to 1943.

The horizons for chemical controls were broadened measurably in 1934 with the announced development of alkyl dithiocarbamate fungicides. However, technical difficulties in development delayed by 10 years making them available to the public. Then in 1943 the dilemma was solved and nabam, zineb and maneb were introduced (the bisdithiocarbamate family of chemicals). These fungicides were broad-spectrum in control of fungal pathogens; production yields in agriculture increased 65% from 1901 to 1945 (a period of 44 years) and by 90% from 1945 to 1954 (a period of 9 years). The bisdithiocarbamates are still used today; however, their availability may be in peril due to the Food Quality Protection Act passed in 1996 by the US Congress.

Chemical soil fumigation, beginning with chloropicrin in 1948 and with methyl bromide in 1951, has been used in indoor and outdoor production of ornamental plants. Excellent control of soil-borne pathogens has been achieved with their use; however, alternatives are being sought due to toxicities associated with their use and their likely elimination for use by 2006.

The use of chemicals to control fungal, nematode and bacterial pathogens from 1945 to 1975 was exciting to plant pathologists and the industry since most disease could be controlled and better and more flowers grown and sold. Prior to 1945 disease control amounted to "putting out fires" and after 1945 it was preventive. Preventive disease control programmes could be designed and successfully performed with proper use of pesticides. Exceptions to this success story were systemic disease and viral-caused diseases. Systemic fungicides and viricides were difficult to develop since the genomes of pathogens and host plants shared some similarities; host and pathogen physiology shares some similar functional responses to some chemical compounds. Thus, pesticides that would control vascular wilts caused by fungi, bacteria and viral pathogens were also probably phytotoxic to the host. For example, prior to 1942 the control of *Verticillium* wilt of chrysanthemums and other vegetatively propagated ornamentals was dependent on selection of stock plants which were visually free from disease, on use of short terminal cuttings and the application of best preventive sprays

[☆]Change History: January 2017. R.K. Horst made edits to the text and updated the references.

This article is an update of R.K. Horst, DISEASE | Overview, *Encyclopedia of Rose Science*, edited by Andrew V. Roberts, Elsevier, 2003, pp. 137–140.

then available. This programme enabled the small grower to avoid disastrous losses, but few were ever free from *Verticillium*. However, during the 1940s and 1950s propagation became concentrated in the hands of a few specialists.

In 1942 A.W. Dimock showed that laboratory procedures for determining the presence or absence of pathogenic fungi and bacteria in the vascular tissues of plants had potential for commercial adaptation. The culture-index was enlarged to include virus-indexing, i.e., culture virus-indexing. The programme also included thermotherapy and meristemtip culture methods for obtaining plants free of virus when detection methods showed them to be infected. The success of the chrysanthemum programme led to similar culture virus-indexing programmes for carnations, geraniums, roses and orchids. These programmes are being used commercially for ornamentals on the European continent as well as in North and South America. These classic programmes have also been modified for use in agronomic crops. The employment of the culture virus-index programme has been so effective that many young growers do not recognize some of the diseases which in 1940 caused costly losses to every chrysanthemum grower in the business.

In 1961 a landmark book was published by Rachel Carson, entitled *Silent Spring*. This book had a major impact on the indiscriminate and successful use of pesticides. The main focus was on DDT and toxic environmental influences of its use. Public concerns raised by this book caught the attention of the US government which took action to establish the US Environmental Protection Agency (EPA) in 1970. The EPA's responsibility was to register and regulate the use of pesticides. These restrictions required exceptional planning in ornamental production.

During the 1980s there was increased interest in the reduced use of toxic pesticides in the environment. These concerns generated more interest in the use of integrated pest management (IPM). The main objective of IPM is to reduce the use of toxic chemicals which contaminate the environment and still control diseases. An important component of a successful IPM programme is the forecast of conditions which are favourable for disease epidemics and to spray only when necessary. IPM strategies which can be used include the following:

- Apply pesticides only when necessary.
- Make use of application methods that apply less pesticide or use a more efficient spray system.
- Use biocompatible chemicals as they become available.
- Use biological controls when available and when appropriate.
- Use cultural practices which are favourable to healthy plant growth.

A successful IPM programme depends on four basic techniques:

1. Scouting: regular and random visual observations provide early warning to disease problems.
2. Disease identification: the first and most important step is to identify the problem; misdiagnosis results in improper control.
3. Timing: improper timing of control measures will result in disease control failure; the control measure must be timed correctly to the stage of disease development.
4. Records: brief accurate records are a good tool for disease control decisions.

A grower's use of IPM strategies can reduce pesticide use by 50%. During the mid-1980s and into the 1990s there has been intense interest in the development and use of biological controls, genetically engineered disease-resistant plants, biocompatible chemicals and more efficient spray delivery systems. Biological controls have been developed from species of *Trichoderma*, *Streptomyces* and *Gliocladium* for control of fungal-caused diseases. Biocompatible chemicals are "soft" chemicals and/or "natural" substances that may bear profound antimicrobial properties and that exhibit low mammalian and environmental toxicities. Some examples are bicarbonates (used in baking), neem from the neem tree (*Melia azedarach*), horticultural oils and strobilins (from mushrooms). There has also been interest in improved efficiency in spray delivery systems, such as air-assisted aerosol generators and air-assisted electrostatic sprayers. Fungicides are dispersed effectively and at reduced dosages.

On 6 August 1996 the US Congress passed the Food Quality Protection Act. This Act requires EPA to reassess tolerances of all 9600 pesticides available to the industry. Thirty-three percent of these pesticides must be reevaluated by August 1999, 66% by 2002 and all of them by 2006. The impact this process will have on the ornamental industry will be great since it is likely that many commonly used pesticides will be eliminated for commercial use. Alternative disease control measures will become more important and in some instances disease control will be difficult. Growers and plant pathologists will need to develop creative disease control strategies to be successful in a very competitive ornamental market.

Glossary

Kerogen Carbonaceous organic matter in rocks, typically composed of interlinked polycyclic aromatic hydrocarbons.

Permineralization A process of fossilization that produces a mineral-infused inorganic-organic mix that can preserve physically robust structures such as organic-rich cell walls.

Phanerozoic The segment of geological time extending from the earliest appearance of shelly invertebrate animal fossils, ~550 million years ago, to the present.

Precambrian The segment of geological time extending from the formation of the planet, ~4500 million years ago, to the beginning of the Phanerozoic.

Stromatolite A laminated rock structure, commonly composed of carbonate minerals, formed by the microbially mediated accretion of laminae from the surface of an ancient seafloor or lake bottom.

Fossil Evidence of Ancient Microbes

Overview of the Fossil Record

As is shown in Fig. 1, geological time is divided into two major segments: the Precambrian Eon, the longer of the two segments that spans the earliest seven-eighths of Earth history and begins with the formation of the planet ~4500 million years ago; and the Phanerozoic Eon, a younger and much shorter segment that extends from the first appearance of shelly invertebrate animal fossils, ~550 million years ago, to the present. The science of paleontology is focused primarily on the fossil record of Phanerozoic, megascopic plants and animals. Because of their economic importance to the petroleum industry in the search for gas and oil, the fossil records of various groups of Phanerozoic microscopic protists (eg, foraminiferans, radiolarians and coccolithophorans) and of the spores and pollen of fossil plants have been intensively studied. But the Phanerozoic record of many other groups of microscopic fossils, most notably including that of fossil microbes, is largely undocumented.

In contrast to the Phanerozoic microbial fossil record, that of the earlier Precambrian is voluminous, known from hundreds of deposits and more than a thousand described taxa, showing that Precambrian microbes were abundant, ubiquitous, metabolically diverse, and biotically predominant. Nevertheless, this early fossil record, virtually all of which has become known since the mid-1960s, is far from complete. Due to the “geologic cycle,” the repeated sequence of mountain-building, erosion, and deposition into sedimentary basins of eroded mineral grains thus produced, the average “lifetime” of a geological unit is ~200 million years. The rock record that has survived to the present therefore peters out with increasing geologic age (Fig. 1). Thus, although the fossil record of cellularly preserved microbes extends far into the Precambrian – throughout all of the Proterozoic (~550 to 2500 million years ago) and much of the Archean (>2500 million years ago) – in units older than ~2000 million years the known record of preserved microbes becomes increasingly sparse and patchy, and the history of the various fossil lineages becomes increasingly difficult to decipher.

Stromatolites

Stromatolites are laminated rock structures, most commonly composed of carbonate minerals (eg, calcite, CaCO₃), that formed by the microbially mediated accretion of laminae, layer upon layer, from the surface of an ancient seafloor or lake bottom. Their layered structure reflects the photosynthetic metabolism of the mat-building microorganisms. The thin (millimeter-thick) mats

[☆]*Change History:* April 2016. J. William Schopf modified the spelling of “Palaeontology” in title; added new Keywords and Glossary; made amendments and updates to text and “Further Reading” section; New sections of text added: III.C.2 Sulfuretum Fossils of Uncertain Systematic Position; IV.A.1 Cyanobacteria; IV. A.2 Sulfur-cycling Bacteria; revised Figure 1 and added Figure 13.

This article is an update of J.W. Schopf, Paleontology, Microbial, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 390–400.

Fig. 1 The known fossil record of Bacteria, Archaea, microbially laminated stromatolites and surviving rock units over geological time.

formed as such microbes multiplied and spread across surfaces and were subsequently intermittently veneered by detrital or precipitated mineral grains that blocked sunlight. To maintain photosynthesis, mobile members of such communities, such as gliding cyanobacterial oscillatoriaceans, moved upward through the accumulated mineral matter to establish a new overlying microbial mat. The repeated accretion, compaction and subsequent lithification of such mats, their microbial community commonly augmented by an influx of non-mobile microbes (such as chroococcacean, entophysalidacean, and pleurocapsacean colonial cyanobacteria) can result in the formation of stromatolitic structures that range from small millimetric columns and pustular mounds to large, decimetric, bioherms. During diagenesis, the series of changes that lead to the lithification of such deposits, silica (SiO_2) or, more rarely, phosphate-containing minerals, can replace the initially deposited carbonate grains. If replacement occurs early, before the mat-building microorganisms decay and disintegrate, cellularly intact microbes can be preserved. However, the great majority of stromatolites, unchanged by such replacement, are devoid of fossil microbes: during diagenesis, carbonate grain growth crushes and obliterates the stromatolite-forming microbes, leaving only an amorphous thin coaly residuum of microbe-derived carbonaceous matter.

Cellular Fossils

Two principal processes preserve cellular microbial fossils: compression and permineralization. Compression-preserved microbes occur in fine-grained detrital sediments such as shales and siltstones, pressed and flattened along bedding planes as the sediment lithified. Such fossils are rare in sediments of the Phanerozoic, evidently due to the bioturbation of such deposits by invertebrate metazoans, but are well known from the Precambrian.

The microbial fossil record is best known from microorganisms preserved by permineralization. Of all modes of fossil preservation, this process (known also as “petrification”) provides the most faithful representation of original biologic morphology. Such preservation, common for plants and fungi as well as fossilized microbes, results from the pervasion of mineral-charged solutions into cells during the early stages of diagenesis, prior to their disintegration. The permeating fluids infill micellar, intercellular, and intracellular spaces – replacing the watery milieu of their biomolecular components – to produce a mineral-infused inorganic–organic mix that can preserve physically robust structures such as organic-rich cell walls. As a result, both the organismal morphology and cellular structure of such fossils can be preserved in microscopic detail. Although permineralized microbes have been reported from a variety of matrices (eg, quartz, carbonate, apatite, and gypsum), the most common such matrix is quartz (silica), the primary mineral that comprises the rock-type known as chert or flint. Hundreds of microbe-preserving cherts are known from the Precambrian when silica was abundant in the world’s oceans, well before the Phanerozoic appearance of silica-mineralized sponges, diatoms and radiolarians that today mediate the oceanic silica budget. Such cherts can contain exquisitely preserved fossil microbes.

Stromatolites: Lithified Microbial Mats

Carbonate microbial stromatolites occur today (Fig. 2A, B, D) that in shape, size, environmental setting and laminar structure are much like those known from the geological past (Fig. 2C–F). In Phanerozoic sediments, fossil stromatolites are rather uncommon, evidently due to the disruption of stromatolite-forming microbial mats by grazing and burrowing metazoans. But in shallow-water carbonate deposits throughout the Precambrian such structures are abundant and morphologically diverse, known earliest from rocks ~3500 million years old (Figs. 2F, 3 and 4). Their distribution over time parallels that of the fraction of the originally deposited Precambrian rock record that has survived to the present: stromatolites are common in younger-aged Precambrian

Fig. 2 Modern and fossil stromatolites. (A) Modern stromatolites at Shark Bay (Hamelin Pool), Western Australia. (B) Modern Shark Bay columnar and domical stromatolites for comparison with (C) fossil stromatolites from the ~2300-Ma-old Transvaal Dolomite, Cape Province, South Africa. (D through F) Modern and fossil vertically sliced columnar to domical stromatolites showing accretionary microbial lamination from Shark Bay (D), the ~1300-Ma-old Belt Supergroup of Montana (E), and the ~3350-Ma-old Fig Tree Group of the eastern Transvaal, South Africa. Scale for (A) and (C) shown by the geologic hammers enclosed by red circles.

Fig. 3 Archean-age microbially laminated stromatolites. (A) Domical, pseudocolumnar and branching stromatolites, overlain by rippled sediments, and (B) a domical stromatolite, from the ~2723-Ma-old Tumbiana Formation, Fortescue Group, Western Australia. (C) Conical stromatolite, and (D) stratiform and conical stromatolites, from the ~2985-Ma-old Insuzi Group, South Africa. (E through G) Laterally linked conical stromatolites from the ~3388-Ma-old Strelley Pool Chert of Western Australia.

Fig. 4 Comparison of the temporal distribution of the 48 Archean-age stromatolite-bearing rock units now known (●) with that of Archean-aged rocks that have survived to the present (cf. Fig. 1).

deposits but become more rare as the rock record peters out with increasing age (Fig. 4). Such structures establish the presence of flourishing photosynthesis-based microbial communities, but because of their carbonate mineralogy they do not contain cellular fossils that might indicate whether the stromatolite-building photoautotrophs were oxygenic, like cyanobacteria, or anoxygenic, like photosynthetic bacteria.

Cellular Microbial Fossils

Taxonomy

Paleontological taxa

Although current microbial classifications are based primarily on biomolecular data (eg. rRNA-, genome-, and DNA base-compositions), for many modern microbial taxa such assignments are consistent with traditional morphology-based groupings. For example, cyanobacteria, the principal stromatolite-formers over geologic time, have been assigned on the basis of their pattern of structure and development to five “sections” (cf. morphology-defined taxonomic families) that for many genera mesh well with biochemically based classifications. Section I (cf. Chroococcaceae) is comprised of predominantly spheroidal, solitary and colonial unicellular cyanobacteria that reproduce by fission or by budding. Section II (cf. Pleurocapsaceae) consists of unicellular or pseudofilamentous forms that by multiple fission give rise to small daughter cells (baeocytes). Section III (cf. Oscillatoriaceae) encompasses uniseriate cyanobacterial filaments that lack cellular differentiation (eg. *Oscillatoria* and *Spirulina*). Section IV (cf. Nostocaceae) includes simple uniseriate filaments that exhibit cellular differentiation into akinetes and heterocysts. Section V (cf. Stigonemataceae) is composed of morphologically more complex filamentous cyanobacteria that exhibit true branching and heterocysts. Representatives of all of these groups are known from the fossil record, Sections I–IV dating from well into the Precambrian (Fig. 1) whereas representatives of Section V are known earliest from *Stigonema*-like fossils of ~400 million-year-old Rhynie Chert of Scotland. In general, Sections II, IV and V are consistent with biochemically based phylogenies whereas cyanobacteria included in Sections I and III do not appear to comprise monophyletic lineages. Nevertheless, because the biochemical components of microbes, like those of all living systems, are geochemically labile – converted over geological time to coaly kerogen, a complex mix of interlinked polycyclic aromatic hydrocarbons – the classification of such fossils is necessarily based on their morphology, not on their original biochemistry.

Identification of the major fossil types

As is shown in Fig. 1, four major categories of ancient microbes are known from the fossil record: (1) cyanobacteria; (2) fossils of uncertain systematic position (*Bacteria Incertae sedis*); (3) sulfur-cycling, including sulfate-reducing bacteria; and (4) methane-producing archaeans. Of these, the microbial fossils *Incertain sedis* are all regarded as members of the Bacterial rather than the Archaeal Domain, the uncertainty of their systematic position reflecting their morphological similarity both to cyanobacteria and to

members of other bacterial groups. The sulfur-cyclers and the methane-producers are known only or predominantly from isotopic evidence, not from morphologically preserved microscopic fossils. Of the four categories, cyanobacteria have the best documented fossil record, known from thousands of cellularly preserved specimens. Many such cyanobacterial fossils are essentially indistinguishable from their modern morphological counterparts in life cycle, behavior, and ecologic setting.

In comparison with other microbes, whether bacterial or archaeal, most cyanobacteria have somewhat larger cells and more complex morphology. Because of their light-requiring oxygenic photosynthetic metabolism, cyanobacteria occupy the uppermost surface of microbial mats, rather than lower regions of such biocoenoses where decay and cellular disintegration are prevalent. For this reason, cyanobacteria have a higher probability of becoming incorporated in the fossil record as cellularly intact specimens than do other prokaryotes, especially if they are preserved by permineralization during the early stages of sediment lithification. Of the various morphological components of cyanobacteria, extracellular sheaths and envelopes, initially composed largely of pentose sugar-containing carbohydrates and relatively resistant to degradation, are the most commonly preserved. Although physically robust and organic-rich cell walls are somewhat less commonly preserved, and in the cells of fossilized filamentous forms the originally peptidoglycan-containing lateral walls are much more commonly preserved than their peptidoglycan-deficient transverse walls. The organic components of the aqueous cytosol of such cells are never preserved intact. Along with their watery milieu, such organics are usually leached out of the cells during preservation, but small aggregates of intracellular carbonaceous remnants occur in some cyanobacterial fossils.

Cyanobacteria

Coccolidal and ellipsoidal fossils (Chroococcaceae, Entophysalidaceae, Pleurocapsaceae)

In Fig. 5 are shown photomicrographs that illustrate the morphological similarities of extant coccolidal and ellipsoidal cyanobacteria (Chroococcaceans, Entophysalidaceans, and Pleurocapsaceans; Fig. 5A, E, G, respectively) to their fossilized counterparts (Fig. 5B, F, H). Fig. 5C shows an image of a sheath-enclosed chroococcacean colony within a thin slice of rock, obtained by the use of confocal laser scanning microscopy (CLSM), for comparison with an optical image of the same specimen (Fig. 5D). Use of CLSM provides high-resolution three-dimensional images of such rock-embedded fossils unavailable from standard photomicrography. The morphological similarity of the fossil and modern cyanobacteria shown in Fig. 5 is typical of Chroococcaceans, Entophysalidaceans and Pleurocapsaceans generally, groups that have established fossil records dating from more than 2500 million years ago (Fig. 1).

Fig. 6 shows a fossil stalk-forming pleurocapsacean that provides evidence of its life cycle (inferred from specimens preserved at varying stages in its development), light-seeking “behavior” (evidenced by the orientation of its elongate stalks), and ecologic setting (documented by paleoenvironmental facies relationships). Like its modern morphological and ecological counterpart, *Cyanostylon* of the Bahamian tidal banks, this ancient pleurocapsacean colonized surfaces by producing laterally extensive pincushion-like aggregates. The virtually identical morphology, life cycle, behavior, and ecologic setting of this fossil pleurocapsacean and its living counterpart are typical of the coccolidal and ellipsoidal cyanobacteria known from the geologic record.

Filamentous taxa (Oscillatoriaceae, Nostocaceae)

Like coccolidal and ellipsoidal cyanobacteria, modern and fossil filamentous members of the group commonly exhibit essentially identical ecologic settings and organismal and cellular morphologies. Among the several extant families of filamentous cyanobacteria, stromatolite-building members of the Oscillatoriaceae have the most extensive fossil record, represented by diverse fossils in hundreds of ancient microbial communities (eg, Fig. 7). However, detailed studies of fossil oscillatoriaceans show that their optically discernable morphology (Fig. 7B, D, F, H) does not always accurately reflect their true structure. In modern oscillatoriaceans, cells divide by the centripetal invagination of partial septations that fuse in the center of a cell to produce transverse cell walls (Fig. 8). The lateral cell walls of such filaments are about twice the thickness of their transverse walls, and they contain rigidifying peptidoglycans that are absent from partial septations and transverse walls except at the cell periphery. Because of these differences, lateral cell walls tend to be relatively well preserved in fossil specimens whereas transverse walls, and their precursor partial septations, are preserved only in part. A fossil oscillatoriacean that exhibits such differential preservation is illustrated in Fig. 9 in which an optical image of the specimen (Fig. 9C) is compared with images obtained by use of CLSM (Fig. 9D–H) and three-dimensional Raman imagery (Fig. 9I–K). The Raman images show that the biopolymers originally comprising the cell walls have been converted to carbonaceous kerogen. They and the CLSM images also document the presence of thin incompletely preserved partial septations, showing that this ancient oscillatoriacean divided by the same processes, and in a living state evidently exhibited the same wall structure composed of the same biochemicals, as extant members of the family. Data such as these establish that the fossil record of the Oscillatoriaceae extends deep into geological time (Fig. 1) and that such cyanobacteria have changed little in form, function and metabolic requirements over thousands of millions of years of evolutionary history.

In comparison with the fossil record of oscillatoriaceans, that of similarly filament-forming nostocaceans is poorly known. A prime characteristic of the Nostocaceae is the presence of intercalary heterocysts, thick-walled cells that protect from oxidation the nitrogenase enzyme complex used to fix atmospheric nitrogen. Such heterocysts develop when nostocaceans are deprived of other sources of usable nitrogen (viz., nitrate and ammonia). In stromatolitic microbial biocoenoses, however, bacterially generated ammonia is plentiful, so the nostocaceans of such communities, both fossil and modern, are not heterocystous (such differentiated cells being earliest known from *Stigonema*-like Section V fossils of the non-stromatolitic Devonian Rhynie Chert).

Nevertheless, based on organismal and cellular morphology, numerous ancient fossils have been assigned to the Nostocaceae. One such example is shown in Fig. 10B, compared with modern *Nostoc* (Fig. 10A). Fig. 10C–E shows images of a fossil akinete, a

Fig. 5 Modern and fossil coccoidal and ellipsoidal cyanobacteria; all fossils are shown in petrographic thin sections of stromatolitic carbonaceous chert. (A) Modern *Gloeocapsa* sp. reproductive resting cell characteristic of nostocaceans that is known from geologic units dating to ~2100 million years ago. The temporal distribution of the Nostocaceae shown by such fossils fits with other lines of evidence. Geochemical data indicate that a stable oxygen-rich environment became established ~2300 million years ago, before which the nitrogenase-protecting heterocysts of akinete-producing nostocaceans would have been of little selective advantage. Further, rRNA phylogenies indicate that the Nostocaceae, like other heterocystous cyanobacterial families, originated in a burst of evolution well after the appearance of

Fig. 6 Specimens of the colonial stalk-forming pleurocapsacean cyanobacterium *Polybessurus bipartitus* in petrographic thin sections of stromatolitic chert from the ~775-Ma-old River Wakefield Subgroup of South Australia. (G) Interpretive drawings (based on tracings of photomicrographs) showing from (a) through (d) the ontogeny of stalk-formation.

coccoidal, ellipsoidal, and non-heterocystous filamentous oscillatoriaceans. Like other cyanobacteria, nostocaceans appear to have evolved little or not at all since their origination more than 2000 million years ago (Fig. 1).

Bacteria *Incertae Sedis*

Fossils regarded as Bacteria *Incertae sedis* – that is, fossil prokaryotes of the Bacterial Domain that cannot be firmly identified as members of any particular extant microbial group – are known throughout the geological record. Such remnants constitute the great majority of the fossils now known from Archean-age rocks. Because of geologic recycling, and the resulting decrease in the preserved

Fig. 7 Modern and fossil filamentous (oscillatoriacean) cyanobacteria; fossils in (B) and (D) are shown in petrographic thin sections of stromatolitic carbonaceous chert whereas those in (F) and (H) have been separated from their siltstone matrices by acid maceration. (A) Modern *Oscillatoria* sp. for comparison with (B) *Oscillatorioopsis brevicovexa* from the ~750-Ma-old Bitter Springs Formation of central Australia. (C) Modern *Oscillatoria amoena* for comparison with (D) *Cephalophytarion grande* from the ~750-Ma-old Bitter Springs Formation of central Australia. rock record with increasing geological age, the record of Archean fossils is sparse, reported from only some 20 Archean units, 2500 to 3500 million years in age, and represented by fewer than 10 fossil morphotypes. Of these Archean units, all but a few dates from the interval between 3200 and 3500 million years ago, well documenting the existence of microbe-level life at least this early in Earth history. For most of these ancient microbes, the uncertainty in their classification stems from their morphological similarity both to cyanobacteria and to non-cyanobacterial bacteria.

Representative fossils of uncertain systematic position

The specimens shown in Figs. 11 and 12 are representative of the Archean microscopic fossils now known. Rod-shaped fossils (Fig. 11A–F), small-diameter coccoids (Fig. 11G–R), and narrow filaments (Fig. 11S–Y) predominate, but larger-diameter uniseriate cellular microbes also occur (Fig. 12). Certain of the small-celled (Fig. 11A–F) and narrow filamentous forms (Fig. 11, S–Y) seem likely to be non-cyanobacterial bacteria, but others (Fig. 11G–R) have morphologies consistent with their assignment either to relatively large-sized non-cyanobacterial microbes, such as some sulfur-cycling bacteria, or to small-sized cyanobacteria. Similarly, the relatively large-diameter uniseriate trichomes shown in Fig. 12 are morphologically similar to extant and fossil cyanobacteria (eg, Fig. 7A–F) but are comparable also to large-celled sulfur-metabolizing bacteria (eg, *Thioploca* and *Beggiatoa*). A firm taxonomic

Fig. 8 Schematic drawing, based on transmission electron micrographs, of a medial section of a cell of a modern filamentous oscillatoriacean cyanobacterium showing the symmetrically distributed primary and secondary partial septations that with ingrowth give rise to new medial cells. Modified after Pankratz, H.C., Bowen, C.C., 1963., American Journal of Botany 50, 387–399.

Fig. 9 Modern and fossil oscillatoriacean cyanobacteria showing partial septations; (A through C) show optical photomicrographs; (D through H) show confocal laser scanning micrographs; and (I through K) show three-dimensional Raman images (acquired in a spectral window centered in the kerogen “G” band at $\sim 1605 \text{ cm}^{-1}$ that establishes the carbonaceous composition of the fossil). (A and B) Two specimens of modern *Oscillatoria* sp. that exhibit well-defined partial septations (at arrows). (C) Optical image of the morphologically similar fossil *Oscillatoriopsis media*, in a petrographic thin section of stromatolitic chert from the ~ 650 -Ma-old Chichkan Formation of southern Kazakhstan, in which the red rectangles denote the areas of the trichome shown in (D), (E), and (F through K). (D) The trichome terminus, showing its rounded end-cell and subtending disc-shaped medial cells. (E) A part of the trichome that exhibits well-defined partial septations (at arrows). (F through H) A second part of the trichome that exhibits partial septations (at arrows), in (F) showing the trichome as viewed from above its upper surface, in (G) with the image of the trichome tilted slightly to the right to show its interior, and in (H) with the image rotated to show the trichome as viewed from its side. (I) A Raman (chemical) image of the part of the specimen denoted by the red rectangle in (F), as viewed from above the trichome. assignment of such fossils is not yet possible and, given their great age and the vagaries of preservation that preclude their assured linkage to modern microbes, they might be representatives of extinct lineages.

Sulfuretum fossils of uncertain systematic position

Sulfur-isotope data from sedimentary pyrite indicate that sulfate-reducing bacteria were extant ~ 3500 million years ago (Fig. 1). Cellularly preserved communities of such sulfuretum microbes are known from deep-sea sediments, 2300- and 1800 million-

Fig. 10 Modern and fossil nostocacean cyanobacteria; (A through C) show optical photomicrographs; (D and E) show confocal laser scanning micrographs. (A) Modern *Nostoc* sp. (PCC 7936) for comparison with (B) *Veternostocale amoenum* shown in a petrographic thin section of stromatolitic chert from the ~750-Ma-old Bitter Springs Formation of central Australia. (C through E) *Archaeoellipsoides longus*, a reproductive akinete characteristic of nostocacean cyanobacteria, from the ~650-Ma-old Chichkan Formation of southern Kazakhstan, in (C and D) shown as viewed from above the specimen, and (E) shown from its lower side.

year-old units of Western Australia, assemblages of both communities inhabiting similar sub-seafloor environments; both exhibiting distinctive “cobweb-like” microbial fabrics; both being composed of virtually identical microbial components; and both being notably similar to modern sulfur-cycling assemblages abundant in anoxic mud off the coast off South and Central America (Fig. 13). Diverse groups of extant bacteria have been shown to cycle sulfur, most prominently gram-negative Proteobacteria. The phylogenetic affinities of the sub-seafloor modern and fossil sulfur-cyclers (reported in 2007 and 2015, respectively) have yet to be determined.

Carbon- and sulfur-isotopic evidence of ancient microbes

The carbon isotopic record of photosynthesis, based on thousands of analyses, shows that Earth’s ecology has been dominated by autotrophic primary producers since at least as early as ~3500 million years ago. Such data are consistent with carbon fixation by Rubisco (ribulose biphosphate carboxylase/oxygenase), the CO₂-capturing enzyme of cyanobacteria (as well as of photosynthetic protists and higher plants). But because of the mixing of carbonaceous matter from diverse sources that occurs during the deposition of sediments and the alteration of carbon isotopic compositions that can occur during geological metamorphism, these data do not indicate whether in early Earth history the dominant primary producers were cyanobacteria, anoxygenic photosynthetic bacteria, or anoxygenic chemosynthetic bacteria. Other carbon isotopic evidence, measured in carbonaceous matter so enriched C¹² as to be plausibly derived only from CH₄-metabolizing methanotrophs, indicates that anaerobic methanogenic archaeans were present ~3500 million years ago (Fig. 1) and that such microbes were a major component of the ecosystem prior to the establishment of a stable oxygen-rich environment ~2300 million years ago. Similarly, isotopic analyses of sedimentary pyrite (FeS₂), enriched in S³² due to microbial activity, show that sulfate-reducing bacteria were also present in Earth’s earliest biota (Fig. 1). The occurrence of C¹²-rich graphitic carbon in the oldest sedimentary rocks now known, from Akilia Island off southwestern Greenland, suggests that CO₂-using autotrophs may have existed as early as ~3800 million years ago, and similarly C¹²-rich graphite enclosed in ~4100-million-year-old zircon grains, redeposited in younger geological units in the Jack Hills region of southwestern Australia, suggests that microbial life may have existed earlier.

Fossil Evidence of Microbial History

IV.A Evolutionary Stasis

Numerous lines of evidence indicate that microbial communities composed of members of diverse microbial lineages have been extant since early in Earth history (Fig. 1). It seems rather remarkable that the great majority of cellularly preserved exceedingly

Fig. 11 Archean-age bacterial microfossils *Incertae sedis* (of uncertain systematic position), shown in petrographic thin sections. (A through F) Solitary and paired rod-shaped and (G through L) coccoidal unicells from the ~2600-Ma-old Monte Cristo Formation of the eastern Transvaal, South Africa. (M through R) Coccoidal unicells from the ~3260-Ma-old Swartkoppie Formation of Swaziland, South Africa, in (N) through (R) ordered in a sequence inferred to represent stages of cell division (Knoll, A.H., Barghoorn, E.S., 1977. *Science* 198, 396–398). (S) Narrow filamentous fossil from the ~3320-Ma-old Kromberg Formation of Swaziland, South Africa. (T through Y) Narrow filaments (*Archaeotrichion contortum*) from chert units of the ~3470-Ma-old Mount Ada Basalt of northwestern Western Australia.

ancient fossil microbes, hundreds or thousands of millions of years in age, can be related with confidence to members of still-extant lineages. However, such affinities seem unassailable, based not only on the organismal and cellular morphology of members of large populations but, additionally, on patterns of cell division and colony form; fossil-preserved evidence of light-seeking behavior (eg, stalk-growth in pleurocapsaceans, stromatolite-forming gliding motility in oscillatoriaceans); isotope-evidenced metabolic requirements; and geologic evidence of ecologic settings, with representatives of the fossil groups exhibiting the same community fabric and producing the same small-, medium-, and large-scale sedimentary structures as their modern counterparts in the same environments.

Nevertheless, a question arises: Why is it that such microbes, unlike later-evolved plants and animals, have exhibited such notably pervasive evolutionary stasis? A part of the answer is that such microbes are non-sexual, thereby lacking the genetic variability provided by the genetic recombination afforded by later-evolved eukaryotic sexuality. Is this the only explanation? Two microbial groups – cyanobacteria and sulfur-cycling bacteria – may provide an answer.

IV.A.1 Cyanobacteria

Perhaps most striking among such evidence of a lack of change over enormous segments of geological time is that showing the evolutionary stasis of cyanobacteria, the best documented of all ancient lineages. Such stasis may, or may not be characteristic of microbial lineages generally, but for cyanobacteria it is established firmly by the essentially identical morphologies, life cycles, behaviors, and ecologic settings of modern and fossil members of the group. Their early evolutionary success can be attributed to

Fig. 12 Archean-age cyanobacterium-like microfossils *Incertae sedis* (of uncertain systematic position), shown in petrographic thin sections. (A–D) Four specimens of *Primaevifilum septatum* from a chert unit of the ~3465-Ma-old Apex Basalt of northwestern Western Australia. (E) A morphologically similar specimen of *P. septatum* from a chert unit of the ~3470-Ma-old Mount Ada Basalt of northwestern Western Australia.

their photosynthetic production of gaseous oxygen, a toxin to the earlier-evolved anaerobic photosynthetic bacteria with which they initially competed for photosynthetic space. Once established, their evolutionary stasis (their hypobrydytelic rate of evolution) was presumably a result in part of their asexual reproduction and the lack of genetic variability it provides. But the prime source of such stasis seems almost certainly to be a result of their exceptional ecologic tolerance. Over their exceedingly long evolutionary history, cyanobacteria adapted to imperceptibly slow changes in the photic zone environment – from anoxic to oxygenic, UV-rich to UV-deficient, CO₂-rich to CO₂-deficient, short to increasingly longer daylengths and, perhaps, from relatively high ambient temperatures (~60°C) to that of the present-day Earth (~15°C). The genomes of cyanobacteria may thus encode a history of adaptation unparalleled by virtually any microbial lineage.

IV.A.2 Sulfur-cycling bacteria

The long-term evolutionary stasis of sulfur-cycling bacteria, while comparable to that of cyanobacteria, appears to differ in cause. Though members of both groups are non-sexual, genetic variability arising only from rare chance mutations, fossil evidence indicates that by 2300 million years ago sulfur-cycling sulfuretum bacteria occupied deep-sea mud. Thus, whereas coeval cyanobacteria inhabited an exceedingly slowly changing photic zone environment to which they incrementally adapted, sub-seafloor sulfuretum microbes inhabited a geologically “unchanging” environment: cold quiescent deep sea mud below the effects of wave

Fig. 13 Optical photomicrographs of modern and fossil sub-seafloor filamentous sulfur-cycling bacteria; all fossils are shown in petrographic thin sections of “cobweb-fabric” carbonaceous chert. (A, B) Modern large-diameter sulfuretum filaments from anoxic mud off the coast of Chile for comparison with similar fossil filaments from sub-seafloor sediments of the (C, D) ~2300-Ma-old Turee Creek Group Kazput Formation and the (E through G) ~1800-Ma-old Duck Creek Formation, both of Western Australia. (H, I) Modern sulfide-oxidizing bacteria from the Chilean sulfuretum, identifiable by their included sulfur granules, for comparison with similar filaments from the (J) ~2300-Ma-old Kazput Formation and the (K) ~1800-Ma-old Duck Creek Formation. (L through N) Modern small-celled narrow bacteria from the sub-seafloor Chilean sulfuretum for comparison with similar filaments from sulfuretums of the (O through Q) ~2300-Ma-old Kazput Formation and the (R) the ~1800-Ma-old Duck Creek Formation.

action in which there was no light, no day-night cycle, no oxygen and, before the much later emergence of burrowing metazoans, no churning of their enclosing sediments. Although such bacteria were no doubt affected by mutational changes, genetic drift, etc., would have moved their populations away from, not toward, the single adaptive peak of this “static fitness landscape.” And because of lack of competition in this unchanging environment, they have exhibited long-term evolutionary stasis in their form, function and metabolic requirements. Such sulfur-cyclers have therefore been proposed as evidencing Evolution’s Null Hypothesis: “If

evolution is a result of adaptation to a changing physical-biological environment; and if a changing physical-biological environment does not exist; then evolution will not occur."

Whether the marked evolutionary stasis of these two groups of fossils is typical of other ancient microbial lineages, such as methanogens, has yet to be determined.

Glossary

Cortex The cell surface, including the cilia and immediate underlying cytoplasm, extending a micrometer or so into the cell. The ciliate cortex includes the plasma membrane of the cell and a characteristic highly organized cytoskeletal and membranous array immediately under the membrane, all organized around the ciliary rows.

Macronucleus The large, highly polyploid (polycopy) nucleus that is functional during growth and proliferation in ciliate protozoa. This nucleus is transcriptionally active and its expression products determine most of the vegetative phenotype of the cell.

Micronucleus One or more small, usually diploid, nuclei in ciliate protozoa. This nucleus contains centric chromosomes, but the genes in them are not arranged to be capable of transcription, and the micronucleus contributes little to the vegetative phenotype. The micronuclei are a genetic reserve and become active only during nuclear reorganization.

Nuclear reorganization The process of rearrangement of the nuclei in ciliate protozoa, involving sexual events. The existing macronucleus is discarded, the micronuclei enter meiosis, and haploid products participate in nuclear fusion, making a new diploid zygotic nucleus. New macronuclei and micronuclei differentiate from mitotic products of the zygote.

Introduction

Paramecia clearly show the defining characters of the phylum of ciliophoran protozoa: nuclear dimorphism, the possession of two distinct types of differentiated nuclei in a single cell, and the cortex, an elaborate cytoskeletal and membranous array organized around the precisely organized rows of the few thousand cilia on the surface of each cell.

Cells of the genus *Paramecium* are very large, ranging in size from 100 to 300 μm in length and about 20–50 μm in width. In spite of this large cell size, the cell cycle time is typically short: as little as 5 h for small species at 27°C. Culturing of cells is easy, using simple plant extract media inoculated with gram-negative bacteria as food organisms.

A few dozen species of *Paramecium* have been described, all but one from freshwater habitats, around the world. Spores or resistant cysts have not been observed in the genus, so the worldwide distribution of the species is still a mystery. The species in the genus were originally defined and distinguished by classical morphological features. More recent analyses of some of the species indicate that a particular morphotype species could contain, in fact, a collection of genetically isolated groups, meeting the Mayr biological species criteria. The best-studied example of this is the *Paramecium aurelia* species group. From studies beginning in the 1950s, Sonneborn determined that the original morphotype *P. aurelia* was not one species, but contained at least 15 genetically isolated groups with nearly identical morphology. These groups, which he called syngens, were genetically isolated from one another by mating-type nonreactivity and/or hybrid inviability, and were thus distinguishable on that basis. After isozyme gel electrophoresis pattern work in the 1970s provided an independent objective means of distinguishing the syngens, Sonneborn elevated them to full species status. Hence, the original morphotype species *P. aurelia* no longer is valid – One must identify the particular mating type- and isozyme-defined species in the species group.

Cell Structure and Genetics

The two types of nuclei in paramecia are very different in morphology, molecular content, and function.

The small micronuclei are typically diploid, do not appear to be transcriptionally active, and contribute little to the phenotype of the vegetative cell. During mitosis or meiosis, the micronuclei show classical lower eukaryote nuclear behavior of chromosome condensation and formation of a spindle apparatus inside the nuclear envelope. The chromosomes are numerous (some 50–60 in *Paramecium tetraurelia*), very small, and metacentric. For these reasons, no karyotype has been characterized for any of the species. Depending on the species, a cell might possess 1, 2, or 4 or more micronuclei.

Transcriptional expression from the micronuclei is not possible, because the known coding sequences are not in an expression-competent state. The coding sequences of each gene are split by a series of non-coding sequences, known as internal intervening sequences (IES) that split the gene into a series of segments. IESs are short (26–883 bp), unique copy elements inserted into coding and non-coding regions of the micronuclear genome. There are several thousand identifiable in the micronuclear version of the genome. About 45,000 IES have been identified in the micronuclear genome. IES are flanked by TA dinucleotide boundaries – they

This article is a reprint of Karl J. Aufderheide, *Paramecium Molecular Evolution*, *Reference Module in Life Sciences*, Elsevier, 2018.

are not introns, and do not carry typical intron sequence identities. The origin and significance of IES to the species is not understood. They could be 'parasitic' transposon sequences that have promiscuously propagated in the micronucleus.

The large macronucleus is polycopy (i.e., containing 800–1000 copies of each gene – the macronucleus of *P. tetraurelia* contains about 100 pgm of DNA), is transcriptionally active, and determines most of the phenotype of the cell. IES have typically been removed to generate the macronuclear version of the genome. Macronuclear division ('amitosis') involves no elaborate spindle apparatus, no chromosome condensation, and no centromeres. The dividing macronucleus elongates and partitions more or less in half.

The macronucleus is transcriptionally active during vegetative growth and proliferation of the cell, but is discarded during the sexual events known as nuclear reorganization. The micronuclei are the source of genomic material for sexual events, leading to the formation and differentiation of new macronuclei and micronuclei. The macronucleus does not contribute genomic material to reorganization. The parallels of this arrangement to animal germ and soma cell line differentiations are apparent, although in the ciliates, both types of nuclei are contained in a single cell, usually located next to each other.

Sexual reorganization of nuclei in paramecia involves an elaborate 'dance of the nuclei'. Using *P. tetraurelia* as an example, there are two mating types, O and E, and expression of the surface mating reactive proteins is induced by mild starvation. Conjugation can initiate after reactive cells of opposite mating type collide with, and adhere to, one another. After about 1.5 h of loose adhesion and interactions, cells will pair up ventrally into tightly adherent conjugants. Conjugant pair cells remain fused for about 6–7 h at 27°C, during which meiosis and fertilization are accomplished. Pairs then typically separate and complete the nuclear reorganization process individually. Members of the *P. aurelia* species group have a special additional option: if no conjugant partners are available, cells will instead invoke a self-fertilization pathway called autogamy.

With either conjugation or autogamy, nuclear reorganization begins with the fragmentation of the existing macronucleus and entry of the micronuclei into meiosis. All but one of the meiotic products in each cell degenerate, followed by mitosis of the remaining haploid nucleus in each conjugant partner. One of the two resulting haploid nuclei is reciprocally exchanged with the conjugation partner through a conjugation bridge. The two haploid nuclei then fuse to form a diploid fertilization nucleus (zygote nucleus) which then goes through two quick mitotic divisions. The two conjugating cells typically separate at about this time and complete nuclear reorganization individually. Of the four diploid nuclei produced, two differentiate into new micronuclei and two differentiate into new macronuclei.

During formation of the macronucleus from a mitotic product of the zygote nucleus, the chromosomes are fragmented, sequences identified as IES are identified and removed, and the remaining sequences are ligated together and telomerized to produce expression-competent genes located on acentric 'chromosomes' ranging from 50 to 1000 kbp in size. About 15% of the unique sequences in the micronuclear version of the genome are discarded when processed into the macronuclear version. These rearrangements convert the expression-incompetent version of the genes in the micronucleus into the expression-competent version found in the macronucleus. The resulting DNA segments are then replicated manyfold to produce the polycopy macronucleus. After fertilization, the process of macronuclear development takes about 12 h at 27°C.

In autogamy, two mitotic products of the surviving haploid nucleus fuse with each other and reorganization and development proceeds as described above. Conjugation produces two exconjugant cells with identical nuclear genetic content; autogamy produces a cell that is homozygous at all Mendelian loci.

Epigenetics

The genetics and epigenetics of paramecia have been studied for the past 70 years and have been used in developmental genetics studies of many different aspects of the cell. The Mendelian inheritance of the species allows controlled genetic crosses to be readily done, as well as the use of autogamy as the basis for mutant hunts in diverse expressions of the phenotype.

Paramecia also show a number of different fascinating, non-Mendelian, epigenetic inheritance phenomena. A few examples of these illustrate a mechanism by which an old macronucleus influences how the DNA of a developing new macronucleus is processed, potentially altering gene expression from that new macronucleus. Another intriguing phenomenon is the structural inheritance of alterations in the complex cellular cortex organization, by a process that could be considered analogous to the inheritance shown by prion proteins. All of these phenomena and processes are subjects of active investigation and analysis.

The mechanism of epigenetic determination of mating type expression in a macronucleus has been studied in some detail, and is instructive as to one general mechanism of the epigenetic heritability of a differentiated state. In paramecia, mating type is permanently determined as the new macronucleus develops during nuclear reorganization. Expression of either mating type is possible, but, in *P. tetraurelia* and some other species in the *P. aurelia* group, the mating type expressed by the existing macronucleus influences the choice of mating type developing in the new macronucleus, by a process of communication of information through the cytoplasm of the cell undergoing reorganization.

Central to mating type expression is the gene *mtA*. If the cell expresses *mtA*, it is mating type E; if *mtA* is not expressed, the cell is mating type O. After conjugation, the E partner typically differentiates as E when it builds its new macronuclei, and the O partner typically differentiates as O. The difference between the two is whether the *mtA* gene is processed in the developing new macronucleus into an expression-competent state or not. In mating type O cells, the promoter sequence of *mtA* is not present in the macronucleus, and so *mtA*, although present, is not transcribed. In mating type E cells, the promoter sequence is present, and *mtA* is expressed.

The process of mating type determination involves a small RNA molecule survey of the entire genomic sequences in the micronuclei, copied as the micronuclei progress through meiosis, and subsequent comparison of those sequences to small RNA

copies of the corresponding genomic sequences in the existing macronucleus. Sequences identified as micronuclear, but not found in the macronucleus, then migrate into the new developing macronucleus and are used to identify the IES to be removed and discarded from the differentiating genome. In mating type O cells, the promoter sequence of *mtA* is treated as an IES and removed from the new macronucleus; in mating type E cells, the promoter sequence is not identified as an IES and is located correctly to control expression of the coding sequence of *mtA*. Thus, a differentiated genetic state is communicated from the existing macronucleus into the genome of a newly developing macronucleus to replicate that state. This process involves an elaborate use of small RNA sequences from both the micronucleus and the existing macronucleus during reorganization.

Genetic studies have involved a wide range of cellular and developmental mechanisms and processes under both genetic and epigenetic control. Interested readers should refer to the general reviews cited by this article for more information and examples.

Molecular Genetics

The macronuclear genome of *P. tetraurelia* has been sequenced. The genome is unusually AT rich, containing only about 28% G+C content. Out of a total genome size of about 95 Mbp per haploid DNA set, an exceptionally high number of genes (nearly 40,000) have been identified by different estimation methods, indicating a very high density of genes per length of DNA (78% coding density). Only about half of those genes have recognizable similarities to genes from other organisms. The genes identified also contain many introns, most of them being quite small (25 bp average). RNA interference control of gene expression has been identified. Surveys of genomic diversity generated by point mutations indicates an exceptionally low rate of mutational change over time. This suggests that even the short intervening non-coding sequences in the macronuclear version of the genome are under intense selective pressure. These unique features of the paramecial genome, coupled with the unusual codon usage in gene expression (e.g., only one of the three possible termination codons (UGA) is actually used in paramecia; the other two (UAA and UGA) code for glutamine), are characteristic of the phylum Ciliophora and indicate that the ciliates diverged from the evolutionary lineages of other eukaryotes very early in the history of the planet.

Sequence information of the *P. tetraurelia* genome is available from online databases and is currently being used for both forward and reverse genetic/molecular searches, especially relating to the large collection of known Mendelian genes for the species.

Molecular Evolution

Large Scale

Subsequent to the sequencing of the genome of *P. tetraurelia*, analysis of genomic content indicated that the entire genome of the organism has been duplicated at least 3 times in the evolutionary history of the group. After each whole genomic duplication (WGD), there was an apparent extended period of genetic divergence between duplicated sequences, including many thousand sequences being deleted during this sorting-out period. The oldest genomic duplication appears to have predated the evolutionary divergence of *Paramecium* from the near-relative ciliate genus *Tetrahymena*. An intermediate duplication and loss event might be related to the major morphotype species divergences within the *Paramecium* genus. The latest duplication and gene loss event appears to have happened at about the time of species divergence within the *P. aurelia* species group, perhaps as much as 300 million years ago. The significance of these major genomic duplications and subsequent divergence and deletions of genes thus might be correlated with major evolutionary divergence and speciation events. The appearance of the IES in the micronuclear genome appear to have been before the first WGD, and they might contribute to genomic diversity by propagating by transposition and then decaying subsequent to their spread. These possible linkages between WGD, IES, and speciation deserves further study and analyses.

Within the *P. aurelia* Species Group

A more detailed molecular analysis of a limited number of nuclear and mitochondrial genes has been applied to representatives of the 15 members of the *P. aurelia* morphotype species group. It was expected that sequence differences for the selected genes among the different members of the group should reflect the degree of non-reactivity of mating among the species, but this relationship was not apparent. Some apparently closely related species that show some degree of mating cross-reactivity and mating are nevertheless very different in their sequence content for the genes surveyed, while other, more distant species with no mating reactivity show relatively little sequence diversity. These apparently paradoxical results indicate that much more analysis of the processes of mating-type determination and reactivity, versus evolutionary divergence in other parts of the genome, is necessary.

Conclusions

Although paramecia have been known since early days of light microscopy, and they have been intensively studied throughout the nineteenth and twentieth centuries, they still have many intriguing features that warrant further intensive studies well through this new century.

Glossary

Art A work exhibiting human creative skill or workmanship or its application.

Assignee Persons or businesses can acquire an ownership interest in a patent application by assignment from the inventor. The inventor granting the assignment is an assignor. The person or business receiving the assignment is the assignee.

Boolean search A patent search in which Boolean operators like conjunction (and), disjunction (or), and negation (not) are used along with keywords.

Budapest treaty An international treaty signed in Budapest, Hungary, on April 28, 1977, stipulating regulations for depositing microorganisms for patent purpose.

Compulsory license It provides that the owner of a patent or copyright licenses the use of their rights against payment either set by law or determined through some form of adjudication or arbitration.

Infringement The violation of an intellectual property law. Unauthorized use of a patent is an infringement.

Infringer A person/company indulging in patent infringement.

Intellectual property rights An intangible creation of the human mind, usually expressed or translated into a tangible form that is assigned certain rights of property. It is valuable because it provides ownership and exclusive rights to use, manufacture, reproduce, or promote a unique creation or idea.

Nonobviousness A person having ordinary skill in an art would not know how to solve the problem at which the invention is directed by using exactly the same mechanism of the claimed invention.

Novelty The quality of being new and unique.

Patentability Within the context of a national or multilateral body of law, an invention is patentable if it meets the relevant legal conditions. By extension, patentability also refers to the substantive conditions that must be met for a patent to be held valid.

Patent claims Usually present in the form of a series of numbered expressions, or more precisely noun phrases, following the description of the invention in a patent or patent application, and define, in technical terms, the extent of the protection conferred by a patent or by a patent application.

Prior art All information that has been disclosed to the public in any form anywhere in the world about an invention before the priority date of the claimed invention. It includes documentary sources such as publications and nondocumentary sources such as things known or used publicly.

Defining Statement

Patenting of microorganisms requires knowledge about intellectual property rights (IPR), patents, and the legalities of patenting in the home country and abroad by means of multilateral agreements like Trade-Related Aspects of Intellectual Property Rights (TRIPs), the Patent Cooperation Treaty (PCT), and the Budapest Treaty. The procedure for deposition of microorganisms intended for patenting into International Depositary Authorities (IDAs), the mode of operation of IDAs, and the responsibilities of the depositors are outlined. An outline of IDAs and their microbial diversity, patent databases, and strategic mining of patents has been provided.

Introduction

Nowadays, greater significance and coverage is given to intellectual property rights (IPR) and their protection. Intellectual property is a generic term that encompasses all expressions of human creativity. Ownership of intellectual property is usually expressed as “intellectual property rights.” Intellectual property is divided into two categories: industrial property, which includes inventions (patents), trademarks, industrial designs, and geographic indications of source, and copyright, which includes literary and artistic works such as novels, poems, plays, films, musical works, and other artistic works such as drawings, paintings, photographs, sculptures, and architectural designs.

[☆]*Change History*: July 2016. S. Sekar and D. Kandavel updated Abstract, Glossary and Further Reading sections; added Keywords; revised Table 4 and 8 totally; Edits and updates were made throughout the article.

This article is an update of S. Sekar, D. Kandavel, Patenting of Living Organisms and Natural Products, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 35–51.

Among intellectual properties, patents are extremely important. A patentable invention must be “novel, nonobvious, and have utility.” A patent is a set of exclusive rights granted by a state to an inventor or his/her assignee for a fixed period of time in exchange for disclosure of the invention. Patents in the modern sense originated in 1474, when the Republic of Venice enacted a decree by which new and inventive devices, once they had been put into practice, had to be communicated to the Republic in order to obtain the right to prevent others from using them. In 1623 under King James I, England followed the Statute of Monopolies, which declared that patents could only be granted for “projects of new invention.” During the reign of Queen Anne (1702–14), the lawyers of the English Court developed the requirement that a written description of the invention must be submitted. These developments, which were in place during the colonial period, formed the basis for modern English and US patent law. In the United States, during the colonial period and Articles of Confederation years (1778–89), several states adopted patent systems of their own. The first Congress adopted a patent act, in 1790, and the first patent was issued under this act on July 31, 1790.

Any patent has a definite period of life or existence. When the privilege time expires, the patented invention is free to be exploited by others. Patents promote next-generation researchers to further augment/refine the innovation. An invention is free to be exploited in the market if it is not patented. Patenting also prevents the duplication of research. Different kinds of patents exist for different protections. A product patent allows rights (including exclusive manufacturing and marketing rights) relating to the object, while a process patent relates to a means. A design patent protects the ornamental design, configuration, improved decorative appearance, or shape of an invention. This patent is appropriate when the basic product already exists in the marketplace and is not being improved upon in function but only in style; for example, designer eyeglass frames and original Coca-Cola bottles. A utility patent protects any new invention or functional improvements on existing inventions. This can be to a product, machine, a process, or even composition of matter. For example, going from light emitting diode (LED) technology to organic light emitting diode (OLED) would call for a new utility patent. In this case, the material of the light emitting diodes has changed from the synthetic material used in LEDs to organic material in OLEDs.

The System of Patenting

The Process of Patenting

In order to obtain a patent right one has to apply to his/her country's Patent Office and go through examinations to determine whether the application fulfills all the necessary requirements. Patents are technically national, given that the designated authority in each country grants patents in that country. But with many multilateral agreements, like Trade-Related Aspects of Intellectual Property Rights (TRIPs), the Patent Cooperation Treaty (PCT), and the Substantive Patent Law Treaty, patenting systems are increasingly being globalized. An international patent search/examination system mooted by the World Intellectual Property Organization (WIPO) may even bring a confluence of the decision-making processes in many countries. The PCT is an agreement for international cooperation in the field of patents. Through PCT, an inventor of a member country (contracting state) of PCT can ensure priority for his/her invention in all/any of the member countries simultaneously, without having to file separate applications in the countries of interest, by designating them in the PCT application.

The inventor, assignee, or legal representative of a deceased inventor or assignee may make an application either individually or jointly. The inventor is entitled to be mentioned in the patent if he applies for it. Two or more corporations as assignees may make an application jointly. The procedure for granting patents, the requirements placed on the patentee, and the extent of the exclusive rights vary widely between countries according to national laws and international agreements. The Patent Office, which examines all applications from around the world, takes precautionary measures before ultimately granting any patent right. These involve exchange of documents with the applicant to determine which claims, if any, are entitled to be patented. Even for inventions that are monumental, a patent right cannot be obtained naturally unless it is applied for. An application requires that one fill out the forms prescribed in the relevant ordinances and submit them to the respective Patent Office. There are two different legal procedures adopted by different patent offices for granting patent. They are as follows:

First-to-file system

In a first-to-file system, the right to the grant of a patent for a given invention lies with the first person to file a patent application for protection of that invention, regardless of the date of actual invention. Majority of patent office's use only this legal system. Prior to filing, publications on the intended patent should not be done. If the patent details are published, then this would amount to disclosure of information and the patent cannot be filed.

First-to-invent system

United States used a first-to-invent system, in which priority is established through a proceeding to determine which applicant actually invented the claimed invention first. In the first-to-invent system, a lengthy administrative proceeding (an interference proceeding) has to be conducted to determine who actually invented first, if another person also files for the same invention. Interference proceedings can take years to complete (even if there is no appeal to the US Court of Appeals for the Federal Circuit) and require extensive analysis. The America Invents Act signed on September 16, 2011, converted this system to newer “first-to-file” system for patent applications filed on or after March 16, 2013.

An application document submitted to the Patent Office will be checked to see whether it fulfills the necessary procedural and formal requirements. An invitation to correct the document will be made where necessary documents are missing or required

sections have not been filled in. The Patent Office will officially publish the content of an application after a specified period has elapsed from the date of filing. An examiner of the Patent Office, who will decide whether or not the claimed invention should be patented, will carry out an examination. The examiner first checks whether the application fulfills the requirements prescribed by law, that is, whether or not there are any reasons for refusal. These requirements include the following:

- Whether the claimed invention is based on a technical idea that utilizes a law of nature.
- Whether it has any industrial applicability.
- Whether the technical idea existed before the filing of the current application.
- Whether the claimed invention could have been easily invented by a person skilled in the art.
- Whether the claimed invention is liable to contravene public order and morality.
- Whether the descriptions in the specification conform exactly to the requirements for patentability.

If the examiner finds reasons for refusal, a notification to this effect is sent to the applicant. It is the sole responsibility of the patentee to see that someone else is not infringing upon his/her patents. It is the patentee's obligation to file a suit of infringement against the infringer. The patentee does not get any kind of money over the grant of the patent. However, when a patentee sells his/her patented invention or markets it, he gets money. TRIPs mandates a 20 year period of patent protection, which is applicable to the member signatories of the agreement.

Patent Cooperation Treaty

Patent Cooperation Treaty (PCT) is an international patent law treaty administered by the WIPO and concluded in 1970. It provides a unified procedure for filing patent applications to protect inventions in each of its Contracting States. As of July 2016, there were 150 Contracting States to the PCT. Any Contracting State that is a signatory to the Paris Convention for the Protection of Industrial Property can become a member of the PCT. A patent application filed under the PCT is called an international application or PCT application. Single filing of an international application is made at the Receiving National Office (RO) or directly at the International Bureau at the WIPO in Geneva. The applicant can be a national or resident of a Contracting State which is party to the European Patent Convention, the Harare Protocol on Patents and Industrial Designs (Harare Protocol), the revised Bangui Agreement Relating to the Creation of an African Intellectual Property Organization or the Eurasian Patent Convention, the international application may also be filed with the European Patent Office (EPO), the African Regional Industrial Property Organization (ARIPO), the African Intellectual Property Organization (OAPI) or the Eurasian Patent Office (EAPO), respectively. On filing a PCT application the applicants must designate the countries in which they wish to retain the option to file a patent application. There is a fee per country designated up to the first five and after that any number of further countries may be designated without fee. PCT has two phases, an international phase when they are international applications in the International Bureau, and a national phase when they are converted to national patent applications in the designated countries of interest. During the international phase, the designated International Searching Authority (ISA) (a Patent Office authorized by WIPO) conducts a patent search and an International Search Report (ISR) is provided within around 6 months of filing to assist the applicant in deciding whether or not to proceed with patent protection. It is optionally followed by a preliminary examination, performed by an International Preliminary Examining Authority (IPEA). Finally, the relevant national or regional authorities administer matters related to the examination of application (if provided by national law) and issuance of patent. The International Bureau also publishes the patent specification. The PCT is divided into two chapters. Chapter I requires that within 20 or 30 months of the earliest priority date (depending on whether or not the country concerned has adopted the most recent amendments to the PCT), the applicant must enter the national phase, that is, file patent applications in any one or more of the countries initially designated. Chapter II allows 30 months from the earliest priority date for entering the national phase and also requires a designated International Preliminary Examining Authority (authorized by WIPO to conduct international examinations) to conduct a non-binding substantive examination of the patent specification to determine whether it meets the requirements for patentability. It should be noted that certain designated offices have fixed time limits expiring even later than 30 months, or 20 months, as might be the case. The national phase is the second of the two main phases of the PCT procedure. The national phase starts only if the applicant files applications in each country of choice (the "designated office"); just the usual application is filed, either before the expiration of the time limit or together with an express request that it commences earlier. The applicant has sole responsibility for performing the act in due time. The consequences of failure to do so are fatal to the application in most designated states. In each such designated state, the international application has the effect of a national (or regional in the case of regional offices) application with regard to the international filing date and the decision to grant. The PCT does not lead to the grant of an "international patent," which does not exist.

Basis of Microbial Patenting

Patenting of microorganisms is not a new concept. In the brewing and baking industries, yeast has traditionally played an important part and patents for new types of yeast were granted in Belgium in 1833 and in Finland in 1843. Like any other patent, microbial patents should also satisfy novelty, nonobviousness, and utility requirements. In patent terms, "novel" means not previously available in the public domain. For example, a new microorganism (not previously known) isolated from a soil sample would be a potentially patentable invention. If the microorganism is claimed in the patent application in an "isolated" form, that form will be

novel over the previously known mixture of that microorganism with numerous other microorganisms in the soil. In addition, if the same microorganism has some practical use involving inventiveness, then it is eligible for patenting.

A product patent allows rights (including exclusive manufacturing and marketing rights) relating to the object, while a process patent relates to a means. A process patent allows the same products to be produced by different producers with different processes of production, whereas a product patent does not allow any firm except the patent holder to produce a particular product. Thus, it is easier to circumvent the process patent regime by inventing a different process to produce the same product whereas the only way to circumvent the product patent regime is to invent a new (differentiated) product in order to serve the consumers. In microorganisms, product and process patents are more applicable. An example of a product patent is the production of a new macrolide immunosuppressant by the microorganism *Actinoplanace* sp. under novel fermentation conditions (USPTO 5,270,187: 1993). An example of a process patent is the process of production of Penicillin G (benzyl penicillin) in *Penicillium chrysogenum* by expression of the PCL (phenyl acetyl-CoA ligase) gene from *Pseudomonas putida*. PCL gene product converts phenyl acetic acid to phenyl acetyl-CoA and causes an increase in the production of Penicillin G (USPTO 6,251,655: 2001).

A new era was ushered in intellectual property when, in 1980, the US Supreme Court allowed the patenting of a living microorganism intended to soak up oil spills. Even though patent laws were originally framed keeping mechanical and chemical inventions in mind, patenting of life-forms was included under the same umbrella. From microorganisms, patent offices have marched on to grant exclusive monopolies for plants, animals, human cell lines, and even fragments of DNA. Generally, microbes or microorganisms are tiny living things, which are invisible to the naked eye. For the purposes of patent protection, the term microorganism often applies to other types of biological material including cell lines of plants or animals, and not excluding human genetic material. A patent coming under the microorganism category includes different biological material in different countries. For example, even seeds are accepted under the category of microorganisms in some culture collections. The term microorganism is an umbrella term that includes the following:

- Viruses.
- Bacteria, actinomycetes and mycoplasmas.
- Yeasts, filamentous fungi, and mushrooms.
- Protozoa and unicellular algae.
- Undeveloped animal or plant cells (cell lines and tissue cultures).
- Nematodes, embryos and hybridomas.
- Fused cells, transformants, and vectors utilized in genetic engineering (such as plasmids, phage).
- Oncogenes.
- DNA and RNA.

The European Union patents relating to Biotechnological Inventions embraces “biological material” instead of the term microorganism and it means any material containing genetic information and capable of reproducing itself or being reproduced in a biological system which are isolated from its natural environment or produced by means of a technical process even if it previously occurred in nature. Microorganisms are patentable, provided that the microorganisms intended to be patented are deposited in a designated culture collection known as International Depositary Authority (IDA). The status of IDA is conferred by WIPO under the Budapest Treaty to culture collections fulfilling the requirement criteria. The term “microorganism” is not defined in the Treaty; as such, it may be interpreted in a broad sense as depending on the applicability of the Treaty to microorganisms to be deposited under it. Thus, for example, tissue cultures and plasmids can be deposited under the terms of the Treaty, even though they are not microorganisms in the strict sense of the word. The range of materials accepted by different IDAs under the Budapest Treaty often includes the following:

- Cells, for example, bacteria, fungi, eukaryotic cell lines, and plant spores.
- Genetic vectors (such as plasmids, or bacteriophage, or viral vectors) containing a gene or DNA fragments.
- Organisms used for expression of a gene. Expression systems include bacterial, yeast, viral, plant, or animal cell cultures.
- Yeasts, algae, protozoa, eukaryotic cells, cell lines, hybridomas, viruses, plant tissue cells, spores, and hosts containing materials such as vectors, cell organelles, plasmids, DNA, RNA, genes, and chromosomes.

In many countries infectious agents are categorized in risk groups based on their relative risk. Depending on the country and/or organization, this classification system might take the following factors into consideration:

- Pathogenicity of the organism.
- Mode of transmission and host range.
- Availability of effective preventive measures (eg, vaccines).
- Availability of effective treatment (eg, antibiotics).
- Other factors.

Generally, IDAs do not accept microorganisms with a hazard categorization greater than WHO Classification Risk Group 2 (Table 1). In contrast to Risk Groups; Biosafety Levels (BSL) prescribes procedures and levels of containment for the particular microorganism or material (including Research Involving Recombinant or Synthetic Nucleic Acid Molecules). Similar to Risk Groups, BSL are graded from 1–4. BSL 1 commences with low hazard and progressively increases. Standard microbiological practices with no primary barriers can be performed under BSL–1; in BSL–2 in addition certain other precautions like using

Table 1 World Health Organization (WHO) classification of infectious microorganisms by biosafety levels

Risk Group 1 (No or low individual and community risk)
A microorganism that is unlikely to cause hazard to human, animal or environment.
Risk Group 2 (Moderate individual risk, low community risk)
A pathogen that can cause human or animal disease but is unlikely to be a serious hazard to laboratory workers, the community, livestock, or the environment. Laboratory exposures may cause serious infection, but effective treatment and preventive measures are available and the risk of spread of infection is limited.
Risk Group 3 (High individual risk, low community risk)
A pathogen that usually causes serious human or animal disease but does not ordinarily spread from one infected individual to another. Effective treatment and preventive measures are available.
Risk Group 4 (High individual and community risk)
A pathogen that usually causes serious human or animal disease and that can be readily transmitted from one individual to another, directly or indirectly. Effective treatment and preventive measures are not usually available.

personnel skilled in handling pathogenic agents, secluded laboratory, proper disposal of contaminated items, etc., are to be followed and it is suitable for work involving agents of moderate potential hazard to personnel and the environment; BSL-3 involves microbes which are potentially lethal via inhalation and the personnel are provided medical surveillance, offered relevant immunizations, use of biological safety cabinet, wearing solid-front protective clothing and drafting a safety operation protocol for procedures followed; BSL-4 is the highest level of biosafety precautions and is appropriate for work with agents that could easily be aerosol-transmitted within the laboratory and cause severe to fatal disease in humans, the laboratories are set up to be either cabinet laboratories or protective suit laboratories, wearing positive pressure suit and upon exit personnel must pass through a chemical shower for decontamination, then a room for removing the positive pressure suit and followed by a personal shower.

Legal Aspects of Microbial Patenting

WTO and TRIPs Compliance

World Trade Organization (WTO) is an organization for liberalizing trade across the globe and a forum for negotiating trade agreements and trade disputes among nations. It operates on the basis of certain trade rules negotiated and signed by the member governments. These documents provide the legal ground rules for international commerce. Following World War II, the victor nations sought to create institutions that would eliminate the causes of war. Their principles were to resolve or prevent war through the United Nations and to eliminate the economic causes of war by establishing three international economic institutions. The three institutions were the International Monetary Fund (IMF), the World Bank, and the International Trade Organization (ITO).

The US Congress did not object to the establishment of the World Bank and the IMF but refused to agree to the ITO on the grounds that it would cede too much sovereignty to an international body. Because the ITO was stillborn, the provisional agreement for the ITO, the General Agreement on Tariffs and Trade (GATT), became the agreement and the organization for establishing and enforcing, through dispute settlement, the international trade rules. The final and longest GATT round was the Uruguay Round, which lasted from 1986 to 1994 and led to the WTO's creation. As of now, there are 160 member nations. GATT mainly dealt with trade in goods, whereas WTO now deals with agriculture, textiles and clothing, banking, telecommunications, government purchases, industrial standards and product safety, food sanitation regulations, intellectual property, and much more.

The WTO's agreement on TRIPs, negotiated in the Uruguay Round, introduced intellectual property rules into the multilateral trading system for the first time. The WTO's TRIPs agreement is an attempt to narrow the gaps in the way these IPRs are protected around the world, and to bring them under common international rules. It establishes minimum levels of protection that each government has to give to the intellectual property of fellow WTO members. At the same time, additional time has been given to developing countries to fulfill their commitments. The TRIPs agreement says patent protection must be available for inventions for at least 20 years. Patent protection must be available for both products and processes, in almost all fields of technology. Governments can refuse to issue a patent for an invention if its commercial exploitation is prohibited for reasons of public order or morality. They can also exclude diagnostic, therapeutic, and surgical methods for the treatment of humans and animals, plants and animals (other than microorganisms), and biological processes for the production of plants or animals (other than non-biological and microbiological processes). However, any country excluding plant varieties from patent protection has to provide an effective *sui generis* system of protection. The agreement describes stipulates minimum rights of a patent owner. If a patent owner abuses his rights, for example, by failing to supply the product on the market then the governments can issue "compulsory licenses," allowing a competitor to produce the product or use the process under license. But this can only be done under certain conditions aimed at safeguarding the legitimate interests of the patent-holder. Nonpatentable inventions, in general, are given in Table 2.

There are several international intergovernmental organizations in the WTO, which have an observer status, to follow discussions therein on matters of direct interest to them. Some of them under the General Council are the Food and Agriculture Organization (FAO), the IMF, International Trade Center (ITC), the Organization for Economic Cooperation and Development (OECD), the United Nations (UN), the United Nations Conference on Trade and Development (UNCTAD), the World Bank, and WIPO. There is a separate council observing TRIPs. It includes FAO, the IMF, International Union for the Protection of New Varieties of Plants (UPOV), OECD, UN, UNCTAD, the World Bank, the World Customs Organization (WCO), and WIPO.

Table 2 Nonpatentable inventions

-
- An invention that is frivolous or that claims anything obviously contrary to well-established natural laws.
 - An invention, the primary or intended use of which would be contrary to law, or morality, or injurious to public health, including to protect human, animal, or plant life or health, or to avoid serious prejudice to the environment.
 - The mere discovery of a scientific principle or the formulation of an abstract theory. The mere discovery of any new property or new use for a known substance or of the mere use of a known process, machine or apparatus unless such known process results in a new product or employs at least one new reactant.
 - A substance obtained by a mere admixture resulting only in the aggregation of the properties of the components thereof or a process for producing such substance.
 - The mere arrangement or rearrangement or duplication of known devices, each functioning independently of one another in a known way.
-

WIPO and the Budapest Treaty

WIPO is a specialized self funding agency of the UN. The WIPO Convention of the UN established WIPO in 1967, with a mandate from its member states to promote the protection of intellectual property (IP) throughout the world through cooperation among states and in collaboration with other international organizations. WIPO's core tasks include developing international IP laws and standards, delivering global IP protection services, encouraging the use of IP for economic development, promoting better understanding of IP, and acting as a forum for debating various emerging issues. There are currently 188 member states of WIPO (as on July 15, 2016). WIPO administers 26 treaties dealing with IP protection, global protection system, and patent classification. Some of them are the Berne Convention, the Brussels Convention, the Madrid Agreement, the Marrakesh VIP Treaty, the Nairobi Treaty, the Paris Convention, the Patent Law Treaty, the Rome Convention, the Singapore Treaty on the Law of Trademarks, the Trademark Law Treaty, the Washington Treaty, the WIPO Copyright Treaty, the Budapest Treaty, the Hague Agreement, the Lisbon Agreement, the Madrid Protocol, the PCT, the Locarno Agreement, the Nice Agreement, the Strasbourg Agreement and the Vienna Agreement. The Budapest Treaty on the International Recognition of the Deposit of Microorganisms for the Purposes of Patent Procedure (hereinafter referred to as the Treaty) acts as a guide for depositing microorganisms for patenting purposes. The Treaty was concluded on April 28, 1977, and came into force on August 19, 1980. The regulations under the Budapest Treaty were modified in 1981 and in 2002. The Treaty is open to States party to the Paris Convention for the Protection of Industrial Property (1883). Disclosure of the invention is a requirement for the grant of patents. Normally, an invention is disclosed by means of a written description. Where an invention involves a microorganism or the use of a microorganism, disclosure is not possible in writing but can only be effected by the deposit of a sample of the microorganism with a specialized institution. Under the Treaty, a contracting state that allows or requires the deposit of microorganisms for the purposes of patent procedure must recognize, for such purposes, the deposit of a microorganism with any IDA, irrespective of whether such authority is on or outside the territory of the said state. What the Treaty calls an IDA is a scientific institution, typically a culture collection, which is capable of storing microorganisms. Such an institution acquires the status of IDA when the contracting state in the territory where it is located issues assurances to the Director General of WIPO to the effect that the said institution complies and will continue to comply with certain requirements of the Treaty. This treaty will save the depositor's money because deposition with one IDA is sufficient for patent application in any contracting states and it establishes a uniform system of deposit, recognition, and furnishing of samples of microorganisms.

Components of Microbial Patenting

Culture Deposition With IDA

Procedure for deposition

Most patent offices require the deposit to be made no later than the filing date of the relevant patent application (or the priority date if priority is being claimed from an earlier application). However, it is advisable to make the deposit as early as possible and not to leave it until just before the deadline. In total there are 14 forms, numbered BP/1 to BP/14, available under the Budapest Treaty that need to be presented when required. The International Bureau of WIPO has drawn them up. Some of the forms and their usage are given below:

- (BP/4) – Receipt in the case of an original deposit.
- (BP/5) – Receipt in the case of a new deposit.
- (BP/6) – Receipt in the case of a transfer.
- (BP/9) – The form for the viability statement.

These forms are called “international forms” and relate to the receipt and the viability statement. The form numbers BP/1, 2, 3, 7, 8, 10, 11, 13, and 14 are models for use by the respective IDAs. Form BP/12, which relates to the furnishing of samples to the legally entitled parties, is a form whose contents were fixed by the Assembly of the Budapest Union. The fee collected for storage covers the whole duration of storage and thus it is a one-time payment.

Obligations of IDA

The IDA has to have the expertise and facilities necessary to keep the microorganism viable and uncontaminated throughout the storage period required by the Treaty. If for any reason an IDA ceases to function as such, the Treaty provides for the microorganisms

deposited with it to be transferred to another IDA. When the microorganism has been accepted as an original or new deposit, the date of that original or new deposit, as the case may be, shall be the date on which the IDA received the microorganism. Except in the case of a conversion of a deposit made outside the Budapest Treaty under Rule 6.4(d), the date of deposit is held to be the date on which the IDA physically receives the microorganism, even though all procedural requirements for acceptance may not have been met on that date.

Rule 6.4(d) of the Treaty allows for a deposit originally made outside the provisions of the Treaty and before the culture collection became an IDA deposit to be converted to a deposit made under the Treaty. The requirements for converting an existing deposit into a "Budapest deposit" are essentially the same as those that must be met when making an original deposit under the Treaty, except that the microorganism itself, of course, will already have been sent and received. However, it must be realized that when a deposit is converted under Rule 6.4(d), for the purposes of the Treaty, the date of deposit is held to be the date on which the culture collection acquired IDA status, not the earlier date on which the collection physically received the microorganism. It is important that this "artificial" date of deposit be borne in mind in relation to the filing dates of patent applications referring to the deposited microorganism. Following an "understanding" reached by the Assembly of the Budapest Union (in 1981 and in 1990), the depositor may request that a deposit made with an IDA, but outside the scope of the Budapest Treaty, be converted into a Budapest Treaty deposit. Furthermore, according to such "understanding," the date recognized for the purposes of the Treaty as the date of deposit is determined by the applicable national law. In practice this means that whereas some industrial property offices may recognize the date on which the IDA received the microorganism as the date of deposit, others may recognize only the date of receipt of the request for conversion by the IDA. Depositors should bear this in mind and consider any effects it may have on patent applications or patents referring to the converted deposit. In American Type Culture Collection (ATCC), if a deposit has been released for distribution before converting it into a Budapest Treaty deposit, then there cannot be any restriction on its further distribution.

Having received and accepted a microorganism for deposit (or having converted an existing deposit), the IDA has to notify the depositor of this fact by issuing to him/her an official receipt for that deposit (Rule 7.1). The receipt must be made out on the BP/4 form. This form is one of the four "international forms," a model of which has been established by the Director General of WIPO and the Budapest Union Assembly (Rule 7.2(a)). Wherever the regulations specify the use of an "international form" by IDAs, such use is mandatory. After the depositor submits a frozen or freeze-dried sample, the IDA checks the viability of the deposited material. Other essential examinations are also carried out. If the results are good then the IDA preserves the material and a sample is returned to the depositor for verification of properties. A certificate of deposit and viability is provided along with an assigned patent deposit number. The deposit date is set as the date of receiving the viable material. If the results are bad, then the depositor has to supply a fresh deposit again. Any microorganism deposited with an IDA shall be stored by such authority, with all the care necessary to keep it viable and uncontaminated, for a period of at least 5 years after the most recent request for the furnishing of a sample of the deposited microorganism was received by the said authority and, in any case, for a period of at least 30 years after the date of the deposit. The depositary authority is obliged to maintain secrecy regarding the deposit and the nature of the deposited material. No international depositary authority shall give information to anyone whether a microorganism has been deposited with it under the Treaty. It shall not give any information to anyone concerning any microorganism deposited with it under the Treaty except to an authority, natural person or legal entity which is entitled to obtain a sample of the said microorganism under Rule 11 and subject to the same conditions as provided in that Rule. An IDA can refuse to accept a microorganism sent to it, if it is not the kind it accepts under the Treaty or if the IDA is unable to handle the microorganism sent.

Guidelines for the prospective depositor

In addition to making a deposit of the inventive material under the Budapest Treaty, the depositor is required to provide as much descriptive information about the characteristics of the material as is possible at the time of making the application. The type of information will vary with the nature of the material deposited and the invention, as outlined below:

Microorganisms, per se, should be provided with

- Species identification.
- Morphological details such as shape, size, stainability, and motility.
- Colony characteristics, for example, color, shape, size, swarming, and any distinguishing features in appearance.
- Metabolic characteristics including substrate requirements, products or by-products, and isozyme characteristics.
- Genetic characteristics such as specific genes or mutations or their variants (at either the nucleic acid or protein level).
- Plasmids and phage (if any) in the microorganism together with relevant genetic characterization.
- When a mixture of microorganisms is deposited, descriptions of the components of the mixture and at least one of the methods permitting the checking of their presence.

Viruses, plasmids, chromosomes, organelles, and so on, made as deposits within cells, should be provided with

- Sufficient information to enable the cells to be cultured.
- Description of the method of isolation of the virus, and so on, if it is necessary to repeat the invention.
- Any identifying genetic or morphological characterization.

Hybridomas should be provided with information on

- The antigen used for immunization.
- The cells used and method of fusion.
- The criteria used for selection of the clone.

Plant and animal cell lines should be provided with information on

- Clear description of the source of the tissue.
- Procedure used to immortalize the cell line.
- Growth factors and nutrients required in the culture medium.
- Relevant genetic characteristics such as any foreign genes or chromosomes.

The depositor should also provide an “identification reference,” which may be a name, of course, but equally it may be merely a strain designation or even just a laboratory code number. Other than these, a depositor intending to submit a microorganism for deposition should have clear knowledge of the operation methodology of the intended IDA as well as the requirements of a depositor as per the Budapest Treaty before making a deposit (Table 3). It is very important that the depositor find out whether it is possible for him/her to cope with the cost, contracts, regulations, and other modalities of the IDAs. The kind of microorganisms accepted by different IDAs for patent procedures varies. In most of the IDAs across the globe, saprophytic forms are accepted while a few accept viral and other pathogenic forms. Only a few IDAs of the developed countries, like the ATCC, accept all kinds of microorganisms. After deposition, the culture cannot be reclaimed. The depositor should himself/herself keep samples of the culture for the same period of time; so that in case the culture is no longer available from the depositary authority, the depositor can replenish the stock. This deposit is known as New Deposit.

Global IDAs and microorganisms accepted for deposition

Each IDA has the freedom to decide the kinds of biological material it will accept. This mainly depends on the specific expertise of the collection and the equipment available. There are IDAs that accept a broad range of different kinds of biological material, whereas others restrict the kinds of biological material to one or two. Currently, there are 46 such authorities in 24 countries: seven in the United Kingdom, four in the Republic of Korea, three in China, Italy, United States of America and the Russian Federation, two each in Australia, India, Japan, Poland and Spain, and one each in Belgium, Bulgaria, Canada, Chile, the Czech Republic, Finland, France, Germany, Hungary, Latvia, Mexico, the Netherlands and Slovakia. IDAs vary in the kinds of microorganisms accepted for deposition. The National Collection of Yeast Cultures, United Kingdom, accepts only nonpathogenic yeasts for patent deposition. Similarly, Banco Nacional de Algas (BNA), Spain, accepts only algae for patent deposition. This is mainly due to the specialization and expertise of these IDAs in these organisms. But American Type Culture Collection (ATCC) accepts almost all kinds of microorganisms, except nematodes. Microorganisms are highly diverse with variations in metabolic requirements, culture requirements, and so on, and hence handling them requires experience, infrastructure, and detailed scientific knowledge about them. These act as the main factors in some IDAs, restricting the kind of microorganism accepted within their technical purview. Global IDAs and the kinds of microorganisms they currently accept are outlined in Table 4.

Table 3 Information to be known by the depositor prior to deposition

-
- The kinds of microorganisms accepted.
 - Details that must be given in advance of deposition.
 - The official language of communication.
 - Any special transport and/or delivery arrangements.
 - Requirements for furnishing a new deposit or converting a previous deposit into a patent deposit.
 - The state in which the cultures (lyophilized, frozen, liquid suspension, agar slant, etc.) need to be submitted.
 - The minimum number of replicates and minimum titer for each culture required.
 - The time needed by the IDA to carry out viability tests.
 - The manner in which IDA replenishes diminishing stocks.
 - Information about the different kinds of contracts between the IDA and the depositors. Import and/or quarantine regulations.
 - Forms that would be issued by the IDA as official notification.
 - Whether the IDA advises third parties of the correct procedures to be followed in order to make a valid request.
 - Whether the requesting party must meet any health and safety requirements.
 - Whether the samples furnished by the IDA are from its own preparations or from those supplied by the depositor.
 - The fees payable under and outside (eg, safe deposits) the Budapest Treaty provisions.
 - Availability of detailed guidance booklet from the IDA.
-

Table 4 Global IDAs and the kinds of microorganisms accepted

<i>Country</i>	<i>IDA</i>	<i>Kinds of microorganisms accepted</i>
Australia (AU)	National Measurement Institute (NMI) Lady Mary Fairfax CellBank Australia (CBA)	Bacteria (non-pathogenic), yeasts and fungi (non-pathogenic) Animal cell cultures, human cell cultures and hybridomas
Belgium (BE)	Belgian Co-ordinated Collections of Micro-organisms (BCCM)	Animal cell cultures, bacteria (pathogenic and non-pathogenic), fungi (pathogenic and non-pathogenic), human cell cultures, hybridomas, plasmids (either in hosts or not), RNA and yeasts (pathogenic and non-pathogenic)
Bulgaria (BG)	National Bank for Industrial Microorganisms and Cell Cultures (NBIMCC)	Animal viruses, animal cell cultures, bacteria (non-pathogenic), fungi (non-pathogenic), hybridomas, plant viruses, plasmids (in hosts) and yeasts (non-pathogenic)
Canada (CA)	International Depositary Authority of Canada (IDAC)	Animal viruses, animal cell cultures, bacteria (pathogenic and non-pathogenic), bacteriophages, eukaryotic DNA, fungi (pathogenic and non-pathogenic), hybridomas, (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
Chile (CL)	Colección Chilena de Recursos Genéticos Microbianos (CChRGM)	Bacteria (non-pathogenic), fungi (non-pathogenic), molds, plasmids (in hosts) and yeasts (non-pathogenic)
China (CN)	China Center for Type Culture Collection (CCTCC)	Algae, animal viruses, animal cell cultures, bacteria (pathogenic and non-pathogenic), bacteriophages, eukaryotic DNA, fungi (pathogenic and non-pathogenic), human cell cultures, hybridomas, molds, mycoplasma, nematodes, oncogenes, plant cell cultures, plant viruses, plasmids (either in hosts or not in hosts), protozoa (non-parasitic), seeds, and yeasts (pathogenic and non-pathogenic)
	China General Microbiological Culture Collection Center (CGMCC)	Algae, animal viruses, animal cell cultures, bacteria (pathogenic and non-pathogenic), bacteriophages, fungi (pathogenic and non-pathogenic), mycoplasma, plant cell cultures, plant viruses, plasmids (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
	Guangdong Microbial Culture Collection Center (GDMCC)	Algae, bacteria (pathogenic and non-pathogenic), fungi (pathogenic and non-pathogenic), molds, plasmids (in hosts), seeds and yeasts (pathogenic and nonpathogenic)
Czech Republic (CZ)	Czech Collection of Microorganisms (CCM)	Bacteria (pathogenic and non-pathogenic), fungi (pathogenic and non-pathogenic), plasmids (in hosts) and yeasts (pathogenic and non-pathogenic)
Finland (FI)	VTT Culture Collection (VTTC)	Bacteria (non-pathogenic), fungi (non-pathogenic) and yeasts (non-pathogenic)
France (FR)	Collection Nationale De Cultures De Microorganismes (CNCM)	Animal viruses, animal cell cultures, bacteria (pathogenic and non-pathogenic), fungi (pathogenic and non-pathogenic), human cell cultures, hybridomas, plasmids (in hosts) and yeasts (pathogenic and non-pathogenic)
Germany (DE)	Leibniz-Institute DSMZ – Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH (DSMZ)	Animal cell cultures, bacteria (pathogenic and non-pathogenic), bacteriophages, fungi (pathogenic and non-pathogenic), human cell cultures, hybridomas, mycoplasma, plant cell cultures, plant viruses, plasmids (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
Hungary (HU)	National Collection of Agricultural and Industrial Microorganisms (NCAIM)	Bacteria (non-pathogenic), fungi (non-pathogenic), molds and yeasts (non-pathogenic)
India (IN)	Microbial Culture Collection (MCC)	Bacteria (pathogenic and non-pathogenic), fungi (pathogenic and non-pathogenic), plasmids (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
	Microbial and Gene Bank Type Culture Collection (MTCC)	Bacteria (pathogenic and non-pathogenic), bacteriophages, fungi (pathogenic and non-pathogenic), plasmids (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
Italy (IT)	Advanced Biotechnology Center (ABC)	Animal cell cultures, human cell cultures, and hybridomas
	Collection of Industrial Yeasts (DBVPG)	Fungi (non-pathogenic), and yeasts (non-pathogenic)
	Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia Romagna "Bruno Ubertini" (IZSLER)	Animal viruses and Bacteria (pathogenic and non-pathogenic)
Japan (JP)	International Patent Organism Depositary (IPOD)	Algae, plant cell cultures, protozoa (non-parasitic) and seeds
	National Institute of Technology and Evaluation – Patent Microorganisms Depositary (NITE-NPMD)	Animal cell cultures, bacteria (pathogenic and non-pathogenic), bacteriophages, embryos, fungi (pathogenic and non-pathogenic), human cell cultures, hybridomas, plasmids (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
Latvia (LV)	Microbial Strain Collection of Latvia (MSCL)	Bacteria (pathogenic and non-pathogenic), fungi (pathogenic and non-pathogenic), plasmids (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
Mexico (MX)	Colección de Microorganismos del Centro Nacional de Recursos Genéticos (CM-CNRG)	Algae, animal viruses, animal cell cultures, bacteria (pathogenic and non-pathogenic), bacteriophages, embryos, eukaryotic DNA, fungi (pathogenic and non-pathogenic), human cell cultures, hybridomas, mycoplasma, nematodes, plant cell cultures, plant viruses, plasmids (either in hosts or not in hosts), protozoa (non-parasitic), RNA and yeasts (non-pathogenic)

Table 4 Continued

Country	IDA	Kinds of microorganisms accepted
Netherlands (NL)	Centraalbureau voor Schimmelcultures (CBS)	Bacteria (pathogenic and non-pathogenic), bacteriophages, fungi (pathogenic and non-pathogenic), plasmids (either in hosts or not in hosts) and yeasts (pathogenic and non-pathogenic)
Poland (PL)	Collection of Industrial Microorganisms (IAFB)	Bacteria (non-pathogenic), fungi (non-pathogenic) and yeasts (non-pathogenic)
	Polish Collection of Microorganisms (PCM)	Bacteria (pathogenic and non-pathogenic) and bacteriophages
Republic of Korea (KR)	Korean Agricultural Culture Collection (KACC)	Bacteria (non-pathogenic), fungi (non-pathogenic), plant viruses, plasmids (in hosts), seeds and yeasts (non-pathogenic)
	Korean Cell Research Foundation (KCLRF)	Animal cell cultures, eukaryotic DNA, human cell cultures, hybridomas, plant cell cultures and plasmids (either in hosts or not in hosts)
	Korean Collection for Type Cultures (KCTC)	Algae, animal viruses, animal cell cultures, bacteria (non-pathogenic), bacteriophages, embryos, eukaryotic DNA, fungi (non-pathogenic), human cell cultures, hybridomas, molds, murine embryos, plant cell cultures, plant viruses, plasmids (either in hosts or not in hosts), protozoa (non-parasitic), RNA, seeds and yeasts (pathogenic and non-pathogenic)
	Korean Culture Center of Microorganisms (KCCM)	Animal viruses, bacteria (non-pathogenic), bacteriophages, fungi (non-pathogenic), plant viruses, plasmids (either in hosts or not in hosts) and yeasts (non-pathogenic)
Russian Federation (RU)	Russian Collection of Microorganisms (VKM)	Bacteria (non-pathogenic), fungi (non-pathogenic) and yeasts (non-pathogenic)
	Russian National Collection of Industrial Microorganisms (VKPM)	Animal cell cultures, bacteria (non-pathogenic), bacteriophages, fungi (non-pathogenic), human cell cultures, hybridomas, plant cell cultures, plasmids (either in hosts or not in hosts) and yeasts (non-pathogenic)
Slovakia (SK)	National Research Center of Antibiotics (NRCA)	Bacteria (non-pathogenic), fungi (non-pathogenic) and yeasts (non-pathogenic)
	Culture Collection of Yeasts (CCY)	Yeasts (pathogenic and non-pathogenic)
Spain (ES)	Banco Español de Algas (BEA)	Algae
	Coleccion Espanola de Cultivos Tipo (CECT)	Bacteria (pathogenic and non-pathogenic), fungi (non-pathogenic), plasmids (either in hosts or not in hosts) and yeasts (non-pathogenic)
United Kingdom (GB)	Culture Collection of Algae and Protozoa (CCAP)	Algae and protozoa (non-parasitic)
	CABI Bioscience (International Mycological Institute – IMI)	Bacteria (non-pathogenic), fungi (non-pathogenic), nematodes and yeasts (non-pathogenic)
	European Collection of Cell Cultures (ECACC)	Animal viruses, animal cell cultures, eukaryotic DNA, human cell cultures and hybridomas
	National Collection of Type Cultures (NCTC)	Bacteria (pathogenic)
	National Collection of Yeast Cultures (NCYC)	Yeasts (non-pathogenic)
	National Collections of Industrial, Food and Marine Bacteria (NCIMB)	Bacteria (pathogenic and non-pathogenic), bacteriophages, plant cell cultures, plasmids (either in hosts or not in hosts), seeds and yeasts (non-pathogenic)
	National Institute of Biological Standards and Control (NIBSC)	Animal cell cultures and human cell cultures
Unites States of America (US)	Agricultural Research Service Culture Collection (NRRL)	Bacteria (non-pathogenic), fungi (non-pathogenic), molds, plasmids (in hosts) and yeasts (non-pathogenic)
	American Type Culture Collection (ATCC)	Algae, animal viruses, animal cell cultures, bacteria (pathogenic and non-pathogenic), bacteriophages, embryos, eukaryotic DNA, fungi (pathogenic and non-pathogenic), human cell cultures, hybridomas, molds, murine embryos, mycoplasma, oncogenes, plant cell cultures, plant viruses, plasmids (either in hosts or not in hosts), protozoa (parasitic, pathogenic, and non-parasitic), RNA, seeds and yeasts (pathogenic and non-pathogenic)
	Provasoli-Guillard National Center for Marine Algae and Microbiota (NCMA)	Algae, bacteria (non-pathogenic), bacteriophage and protozoa (non-parasitic)

Mining of Microbial Patents

Searching of Patents

The retrieval of patent information has been made easy by the Internet and now access to different patent databases is possible. Patent mining is the process of searching for meaningful trends, patterns, and relationships among patent records contained in patent databases. It helps to determine the possibility for acquiring a patent and checks of infringement chance. Patent searches are generally of two kinds: preliminary and conclusive or complete. Generally, inventors prefer to conduct a preliminary patent search themselves, but to improve the likelihood that our patent application will be allowed by the Patent Office, we must have a complete patent search conducted. With a complete patent search, a professional patent searcher will conduct an expanded search of issued patents and other relevant literature. The relevant utility patents and/or design patents and other literature will be carefully analyzed by a registered patent attorney to see if the invention is novel and nonobvious. Then the patent attorney

prepares a patentability opinion stating whether the invention is likely to receive a patent. Patent mapping and patent analytics are ways of visualizing patent mining results. There are several free and paid patent databases consisting of billions of patent documents. The databases for which patent search is free include the following major ones: USPTO, Espacenet (EPO), Indian Patent Advanced Search System (inPASS), Japan Patent Office (JPO), PatentScope (WIPO), China Patent Machine Translation system (CPMT), IP Australia and Google Patents. Some paid databases are PatentScout, Relecura, Innovation Q Plus, Thomson Innovation, PlanetPatent and CPA Global which also include inbuilt analysis tools. Patent search helps an inventor to determine if a particular invention is unique, to identify potential features for new product, to identify other possible uses for a new product, to determine independent inventors or companies currently or historically obtaining patents in a particular area, to find the patent(s) for a particular invention, to determine the state of the art in a particular area, to study the rate of innovation in a particular area, to identify potential licensees, to identify additional reference materials (journal articles, books, product literature) of use to those working in this area, and so on. Public databases have regional Patent data as per their geographic province and a recent attractive trend observed in certain IPOs is to include data of other Patent Offices available for searching. A global patent database search engine in future for member countries as a whole will improve and impact the patenting process more efficient and treaties should include suitable amendments to make this a reality. Earlier, the search fields were greatly assorted across different IPOs and now the search criteria and fields were mostly common among all IPOs. Patent search and analysis is carried out on the basis of a specific objective and can be classified as below:

Theme-based search

Theme searches provide an overview of patents related to our field of interest. These searches are helpful in detecting the recent trends in our technology area and in establishing the direction for research and development.

Patentability search (novelty search)

Patentability search is the first step in the patenting process. A patentability search surveys patents filed in each national intellectual property office to check whether there exist inventions similar to ours. If there is a plan to file an invention in other countries, this search is essential because foreign applications are cost intensive.

Keyword search

This search provides the information of patents retrieved by specific keywords including assignee, inventors, organism name, and product name.

Patent map (patent analysis)

Quantitative analysis based on statistical data of bibliographic information (country, assignee, International Patent Classification code, etc.). Qualitative analyses of core patents, technological road map, multifarious analysis, and so on, are also included.

Right-to-use searches

Right-to-use searches are conducted, prior to marketing a new product, to confirm that the new product does not infringe on an existing patent or potentially infringe on a patent application.

Public Databases

IP Australia

IP Australia is the Australian Government agency responsible for administering patents, trademarks, designs, and Plant Breeder's Rights. The Patent Enquiries system is known as AusPat and it enables one to access bibliographic and status information about Australian patents and patent applications filed since January 1979. In some cases, details of patents filed before that date are also available. An eDossier with access to a suite of documents relating to the prosecution of patent applications dating back to 2006 is Open to Public Inspection (OPI). Three levels of search are available and can be used based on the details available.

State intellectual property office of China

The former body of the State Intellectual Property Office (SIPO) is the Chinese Patent Office, founded in 1980. In 1998, when governmental bodies were undergoing reforms, the name of the Chinese Patent Office was changed to the State Intellectual Property Office, which is directly subordinated to the State Council. Now, the Patent Office is affiliated to the SIPO. As of 2015, it has collected patent records and abstracts from 104 countries (regions) or organizations, images from 103 countries (regions) or organizations, and texts from 33 countries (regions) or organizations. Among them, the number of documentation on Chinese patents has surpassed 15 million. Two databases on Invention and Utility Model are available to choose with.

Espacenet (European patent office, EPO)

The Espacenet provides a uniform application procedure for individual inventors and companies seeking patent protection in up to 39 European countries. It is the executive arm of the European Patent Organization and is supervised by the Administrative Council. Established in 1977 by the European Patent Convention (EPC) with the aim of creating a centralized patent application and grant system on behalf of all contracting states, the EPO's mission is to support innovation, competitiveness, and economic growth for the

benefit of the citizens of Europe. The EPO examines and grants “European patents,” which, subject to formal requirements, then acquire the same status and influence as national patents under the national laws of such EPC contracting states as the applicant designates. In each contracting state for which it is granted, a European patent gives its proprietor the same rights as would be conferred by a national patent granted in that state. If its subject-matter is a process, protection is extended to products directly obtained by that process. Any infringement of a European patent is dealt with by national law. If the application discloses nucleotide or amino acid sequences (unbranched sequences of four or more amino acids or unbranched sequences of ten or more nucleotides), the description must contain a sequence listing complying with WIPO Standard ST.25 and presented as a separate part of the description. The sequence listing must be filed in electronic form, ie, in text format (.txt). EPO’s free BiSSAP or PatentIn software, can be used for standardized sequence presentation. For full-text search in the worldwide collections Espacenet supports full-text (FT) search in English, French and German. Combisets, an ordered list of linked Cooperated Patent Classification (CPC) symbols created by patent examiners are now searchable as Smart search. All communications between our browser and Espacenet are encrypted. The users of the European patent system can look up procedural data on European patents and patent applications. The Register provides bibliographic data together with procedural data from the date of publication to the grant of the patent, plus any data concerning opposition and appeal proceedings. Internet access to the Register is free of charge. Further, data from the European Patent Register is published weekly in the European Patent Bulletin, where the bibliographic data relating to published European patent applications and granted European patents is arranged according to a number of reference criteria, including the International Patent Classification, European publication numbers and names of applicants/proprietors. Global Patent Index (GPI), an advanced tool for searching the EPO’s worldwide bibliographic and legal status patent data is also available. With GPI one can get high-quality search results; save time when performing long and complex searches; re-use queries; identify technical and competitor trends; perform searches in a secure https environment.

Indian patent office

The Indian Patent Office is administered by the Office of the Controller General of Patents, Designs & Trademarks (CGPD TM). This is a subordinate office of the Indian Government and administers the Indian Law of Patents, Designs, and Trademarks. Free searches for awarded patents are available online. The official website provides public search systems for Indian patents, trademarks, and designs, and it also allows users to check the status of patents, trademarks, and geographical indications (GI). The databases on Indian Patent Information available are Ekaswa A, Ekaswa B, and Ekaswa C. The coverage areas of the databases are given below:

- Ekaswa A database – Patent applications filed in India as published in the issues of the Gazette of India (Part III, Section 2) from January 1995 to December 2004.
- Ekaswa B database – Patent applications notified for opposition in the Gazette of India (Part III, Section 2) published from January 1995 to December 2004.
- Ekaswa C Database – Patent applications published in the official Journal of Patent Office published from January 2005 onwards.

The access to the database is online through internet or can also be subscribed as CD-ROM. The Indian Patent Office has a search facility named “Indian Patent Advanced Search System (InPass)” compared to the old Indian Patent Information Retrieval System (IPAIRS) search, with which full text searching is available for published applications as well as for granted patents jointly or separately. PCT publication number was also introduced as new search criteria. For the time being, the new InPASS is still running simultaneously with the old IPAIRS database.

Japan patent office (JPO)

Patent Abstracts of Japan (PAJ) is a database that has English abstracts of patent applications from 1976 to the present. The Japan Patent database contains full-text data of most patents issued from 1993. It also contains Optical Character Recognition (OCR) full-text data of most patents issued from 1986 to 1992. JPO Industrial Property Digital Library database contains Japanese patent information since 1885. Japan Platform for Patent Information (J-PlatPat) run by the National Center for Industrial Property Information and Training (INPIT) provides databases of publications of patent, utility model, industrial design and trademark. The legal status of each application can also be seen through this service. J-PlatPat provides around 100.3 million documents of patents, utility models, designs and trademarks and their relevant information that have been published since the end of the 19th century. Basic information in gazettes can also be retrieved and used in English, with the objectives of reinforcing the protection of rights overseas and as an international contribution.

Korean industrial property rights information service

It contains the entire Korean industrial property rights information since 1948 and an English abstract of Korean patents since 1979. Machine translations of Korean patent and utility model publications are available since 1983. Korean Intellectual Property Rights Information Service (KIPRIS) covers all Korean IP information of Korean Intellectual Property Office (KIPO). KIPRIS is managed by Korea Institute of Patent Information (KIPI). Two types of patent searches are available. They are general search and advanced search. General search provides access to the information based on words, names, or numbers. Advanced search allows specifying the range of search for each field based on keywords, numbers, dates, and names, and/or a combination of these fields for quicker access to the information. KIPRIS provides access to bibliographic data and Korean full text. A fee-based service called K2E-PAT, is

available for users who wish to search the Korean full text using English keywords. Performing a search through the interface is free; however, attempting to open the machine translated text of individual search results will bring up a payment screen.

Russian agency for patents and trademarks

The Federal Institute of Industrial Property (FIPS) incorporated in the structure of the Federal Service for Intellectual Property (Rospatent) is inter alia in charge of issuing and dissemination of official publications of Rospatent. Russian Patent databases – RUPAT01, RUPAT02, RUPAT03, RUPAT04 and RUPAT_NEW contain full-text of Russian Patented Inventions (in Russian) from 1994 to current. RUPAT_Old contain retrospective database of patent documents as facsimile from 1924 to 1993. RUPATABRU contain abstracts of Russian applications and patented inventions in Russian language from 1994 to current. RUPATABEN contain abstracts of Russian patented inventions in English for the same period. IMPIN contain full text of perspective inventions in Russian language from June 2015.

United Kingdom intellectual property office (UKIPO)

Online Patent Information and Document Inspection Service (IPSUM) allow checking the status and access information on UK patent applications. Patent status, up to date information on patents, access some documents from published patent applications, classifications and fields of search used and selected patent applications can be saved using IPSUM. Users can currently only search for patents by publication or application number. A small help box beside the search form describes the correct format for inputting the publication or application numbers. In the full record view of a patent document, users can view the document on Espacenet through a link provided above the document title.

United States patent and trademark office (USPTO)

The USPTO is a federal agency in the US Department of Commerce. Inventors are encouraged to search the USPTO's patent database to see if a patent has already been filed or granted that is similar to the searched patent. Patents may also be searched in the USPTO Patent Full-Text and Image Database (PatFT). The USPTO houses full text for patents issued from 1976 and PDF images for all patents from 1790. Global Patent Search Network (GPSN) enables users to search the full text of multiple international patent collections. The initial collection available is that of Chinese patent documentation from the State Intellectual Property Office (SIPO) of the People's Republic of China. The Patent Application Information Retrieval (PAIR) system helps to retrieve patent application status.

Patent scope search service of WIPO

The Patentscope database provides access to international Patent Cooperation Treaty (PCT) applications in full text format on the day of publication, as well as to patent documents of participating national and regional patent offices. The information may be searched by entering keywords, names of applicants, international patent classification and many other search criteria in multiple languages. Machine translations are available and default translations originate from Google Translate, but alternate machine translation tools such as Microsoft Translator are also available. A cross-lingual search query generating tool is available in PATENTSCOPE interface, termed as "Cross-Lingual Information Retrieval (CLIR) facility." This tool uses a number of cross-lingual dictionaries built in house by WIPO to generate keyword queries in other languages. The language dictionaries are built by using correlation methods between languages from WIPO's corpus of patent documents. The tool also uses a technology discipline filter to help ensure that the meaning of the desired synonym is clear to the system, disambiguating among polysemy. To further ensure that only desired meanings of a word are searched, the tool also generates a basic set of main IPC classes to be included in the search string. WIPO's International Cooperation on the Examination of Patents (ICE) service provides expert assistance, training, and access to collections of patent documents to developing countries – all free of charge. Through the Access to Specialized Patent Information (ASPI) program, patent offices and academic and research institutions in developing countries can receive free or low-cost access to sophisticated tools and services for retrieving and analyzing patent data. The WIPO Centralized Access to Search and Examination (CASE) system enables patent offices to securely share search and examination documentation related to patent applications, facilitating a more effective and efficient international examination process.

Google patents

Google Patents is a search engine from Google that indexes patents and patent applications from USPTO, EPO, WIPO, Deutsches Patentund Markenamt (DPMA), Canadian Intellectual Property Office (CIPO) and SIPO. These documents include the entire collection of granted patents and published patent applications from each database (which belong to the public domain). Presently this is provided as gratis service.

Private Databases

Thomson scientific IP services

Some of the major services offered by this group are enlisted here:

Westlaw IP – It offers the most comprehensive patent, trademark, copyright and trade-secret content and treatises globally, along with cases, court documents and filings, judge and examiner profiles and filing rules.

Derwent World Patents Index (DWPI) – It features global content in English and provides clear titles, abstracts summarizing the novelty of the invention, intellectual corrections to bibliographic errors and applies unique coding and indexing. It can also translate from 29 languages. The invention-based records allow seeing the full global protection for a single invention.

Thomson Innovation – It brings together a comprehensive international patent coverage with intellectual property (IP) analysis tools.

Thomson Data Analyzer – A desktop software which offers interface for managing and extracting business-critical insights from patent and scientific data within in-house or commercial databases. Users can analyze patent data and scientific literature from any structured database directly on their desktop.

IFI claims patent services

The CLAIMS Global Patent Database with more than 100 million patent data records aggregates patent information from over 50 national and international data sources. Data from different sources are normalized and merged into standardized records and available in a single proprietary ST.36-based XML format. New patent documents and updated records are provided. Legal status, US reassignments and referenced images are included.

PatentScout

PatentScout delivers critical patent data from a private, web-based platform. Enables everyone in the organization to conduct patent searches as needed, without the loss of privacy and search logging associated public tools. Free patent search tools can expose the conceived IP strategy to sniffing technology, competitors, and marketers. Searches performed from the organization using public tools are discoverable during litigation.

Relecura

Its patent search and analysis tool offers global patent coverage with translated and full-text data, curated data with high impact visualization and analytics, integrated patent and assignment search for IP commercialization, enterprise version to search internal, unpublished and patent documents, share patent portfolios along with Relecura analytics, auto-bucket patent portfolios with pre-defined criteria and customizable dashboards that can be shared with anyone.

Innovation Q plus

It is innovation discovery and analytics platform that indexes the full text of periodicals, conferences and Standards, which are cited in patents alongside a comprehensive, full text global patent database. The semantic search technology enables anyone to find valuable content that is buried deep in complex patent and technical documents, resulting in more accurate retrieval than a simple keyword search. It allows users to determine patent strengths and weaknesses, evaluate competition, make legal assessments, and leverage IP business intelligence to support critical portfolio management decisions. It eliminates the need to use Boolean syntax to inform retrieval and instead, the system uses a short phrase, a paragraph, or even an entire document to discover highly relevant results and gain insights. The Map tool creates a visual representation of results based on concepts and meanings. Visualizing document relationships lets users find whitespace in the marketplace, see what competitors are up to, and find more licensing and acquisition opportunities.

Planet patent

It examines US and other patents as well as non-patent prior arts. Over 100 million patents and applications from 100 countries were searched and details about collections, infringements, novelty, right-to-use/freedom to operate, state-of-the-art and validity are provided.

CPA global

Services offered include:

PatentScout – delivers patent data from a private, web-based platform without the loss of privacy and search logging associated with free, public tools.

PatentIQ – allows one to keep up-to-date with dynamic IP data. Whether sharing organization's IP status, competitive analysis or search results, the data is provided in an easily consumable format with PatentIQ. Many PatentIQ dashboards can be created and shared.

PatentGuard – a managed service that analyzes a patent portfolio to identify potential patent title issues, reviews the patent due diligence process, and reports measures to repair broken title chains where possible. This diligence software provides portfolio managers with a certified audit report of any existing issues to help assure the asset is properly protected.

Strategies for Efficient Patent Searching

Patent databases of several countries are available online, which can be consulted for patent searching. As an example the seven-step US Patent search strategy, which is based on US Patent Classification, has been outlined in [Table 5](#). Inventors and

Table 5 Seven steps US patent search strategy

Classification

1. Brainstorm keywords related to the purpose, use and composition of the invention.
2. Look up the words in the Index to the US Patent Classification to find potential class/subclasses.
3. Verify the relevancy of the class/subclasses by using the Classification Schedule in the Manual of Classification.
4. Read the Classification Definitions to verify the scope of the subclasses and note “see also” references.

Access full-text

5. Search the Issued Patents and the Published Applications databases by “Current US Classification” and access full-text patents and published applications.

Review and references

6. Review the claims, specifications and drawings of documents retrieved for relevancy⁷. Check all references and note the “US Classification” and “Field of Search” areas for additional class/subclasses to search.

Produced by the US Patent and Trademark Office, no copyright is claimed in the United States in this material.

entrepreneurs spend huge money to do a professional patent search. But, a prior knowledge about patent keywords and classifications will be helpful in devising a personal search strategy. The results can be analyzed using a private software tool and affirmed. There is a help section on the IPOs which gives detailed guideline regarding the search features and has to be gone through. The advantages and limitations of a search engine can be learned through experience. Before searching, it is advisable to check the date from which the data is available. In many search engines, an Advanced Search Page is given which can be used to improve the search quality. The preliminary step in a patent search is to frame the keywords. While framing keywords, terms directly identifying the search item and related terms should be enlisted. If the search term involves a group of organisms like cyanobacteria, the major generic keywords can be “Cyanobacteria,” “blue-green Algae,” “Cyanobacterium,” and “blue-green Alga” (Table 6). A total of 155 patents were obtained using these four keywords in the USPTO database. Of these, 19 patents were overlaps, while the remaining 136 were unique patent hits. This approach of using generic keywords followed by the removal of overlapping patent hits is helpful in obtaining primary data. When a patent search was made using 84 genera of cyanobacterial as keywords, 156 new hits were obtained out of the total 295 hits obtained. When overlaps were removed, 98 new patents in addition to the earlier 136 patents were obtained. Information derived from these patents helped to identify five major areas of cyanobacterial utilization based on the USPTO database. Similar analysis for a bioproduct like “phycobiliproteins” present exclusively in cyanobacteria, cryptomonads, cyanelles, and rhodophytes could end up with 297 patents from global patent databases. The analysis further revealed patents existing on diverse applications of phycobiliproteins and globally patented production technologies. This ultimately helps to identify lacuna and suggests measures for improvement in the patenting of phycobiliproteins toward application and production technologies.

Even for differences in singular and plural forms for the same keyword the number of hits obtained may be different. Published applications are divided into many fields. Narrowing our search with a specific keyword in a specific field will result in a specific hit and can greatly decrease the likelihood of having extraneous documents returned. Some of the available fields are given in Table 7. While searching, Abstract, Claims and Title will yield specific hits. For additional searches “All fields” option can be chosen. When “All Fields” option is used, bulk hits are obtained due to the presence of both related patents and noise patents. Noise patents are patent hits that simply contain the keyword in the text but the patent is not related to the keyword. The noise patents can be excluded by analyzing the titles and contents of the patents to find any possible linkage and relevance to the major keyword. Such patents have to be compared with the patents obtained from the abstract- and claims-based search in order to identify any additional unique patents. This approach helps to obtain a maximum number of patent hits as well as to avoid missing of patent hits from the database.

Table 6 Major search keywords and the resultant hits from USPTO database for the taxonomic group Cyanobacteria

Major search keywords	Abstract- and claims-based search		All fields search
	Number of hits obtained	Number of hits without overlaps to the other keywords	Number of hits obtained
Cyanobacteria	68	68	907
“Blue-Green Algae”	44	37	624
Cyanobacterium	28	17	387
“Blue-Green Alga”	15	14	93
Total	155	136	2011

Table 7 Important fields in a patent search

<i>Some fields in a Patent search</i>	<i>Explanation</i>
Abstract (ABST)	This field contains a brief summary of the published application.
Application Number (AN)	The application number of the patent. This is 15 characters long, for example, 96600006608137.
Applicant (AP)	It is the name of one or more persons or organizations that are registered as proprietor of a patent application. The applicant can also be the inventor.
Claim(s) (ACLM)	This field contains the text of the published application claims. Claims point out and distinctly claim the subject matter that the applicant regards as the invention and define the scope of the published application protection.
Inventor (TI)	It is the name of the person(s) who is/are registered on patent application as the inventor(s).
International Class (IP)	The International Classification(s) the patent has been placed under.
Patent Number (PN)	It is the unique number assigned by the respective Patent Office to a granted application filed by an inventor/applicant.
PCT Information (PCT)	This field contains PCT Information related to the published application.
Title (TI)	It is the title of the Patent.

Conclusion and List of Relevant Webpages

It is quite imperative that a microbiologist have thorough knowledge about IPR with special focus on patents, systems, and procedures in the home country and abroad as a prerequisite for microbial patenting. Further emphasis should be on the legality involved in microbial patenting; the art of efficient mining of patents, the procedures involved in culture deposition with IDA, and awareness on IDA status culture collections. A perusal of key websites of nodal agencies, organizations, culture collections, and patent databases (Table 8) helps a prospective patentee to achieve the goal. Research driven by such patent analysis is also of contemporary relevance.

Glossary

Danger-Associated Molecular Pattern (DAMP) Molecules released by stressed or dying cells that act as endogenous signals of danger and further enhance inflammation and/or cell-death signaling; also known as alarmins.

Inflammation The body's response to stimuli with the potential for harm (such as pathogens, external injuries, or chemicals) and an important component of the innate immune response. Inflammation is mediated by many different immune cells (including neutrophils, basophils, eosinophils, monocytes, and macrophages), which can release inflammatory mediators such as cytokines, chemokines, and lipids. These mediators can affect blood flow, vascular permeability, and fluid production and present as pain, heat, redness, and swelling of surrounding tissue.

Innate Immunity Early and non-specific host defense mechanisms against invading microbial agents. Composed of physical, chemical, and cellular defenses, especially protein cascades and phagocytic cells, that recognize pathogens by specific conserved features and subsequently initiate host defenses to destroy invading pathogens through mechanisms such as inflammation and complement.

Nod-like Receptor (NLR) Cytosolic innate immune receptors characterized by the presence of a nucleotide-binding and oligomerization domain (NOD) or neuronal apoptosis inhibitor protein (NAIP) class 2 transcription activator (C2TA) heterokaryon incompatibility (HET-E) and telomerase-associated protein 1 (TP1) (NACHT) oligomerization domain. This family of proteins has a wide range of functions including acting as sensors of intracellular microbes, in homeostatic tissue regulation, and as regulators of pro-inflammatory signaling mediators.

Pathogen-Associated Molecular Pattern (PAMP) A conserved molecular feature specific to classes of microbes that is discriminatory from the host self. PAMPs may be lipids, proteins, nucleic acid, or metabolites. Non-pathogenic microbial species display many of the same molecular patterns and are referred to as microbe-associated molecular patterns (MAMPs).

Pattern Recognition Receptor (PRR) A germline-encoded receptor capable of recognizing specific PAMPs. PRRs initiate signaling cascades that direct the innate immune response to best respond to the invading pathogen.

Toll-like Receptor (TLR) Membrane-associated PRRs present on/in innate immune cells that are capable of detecting MAMPs and PAMPs from mycobacteria, Gram-negative bacteria, Gram-positive bacteria, viruses, fungi, and parasites; may be present on the external cell membrane or endosomal membrane.

Abbreviations

AD	Activation domain
APC	Antigen presenting cell
ALR	Aim2-like receptor
ASC	Apoptosis-associated speck-like protein
ATP	Adenosine triphosphate
BIR	Baculovirus inhibitor-of-apoptosis repeats
CARD	Caspase activating and recruitment domain
CD	Cluster of differentiation
CLR	C-type lectin receptor
CpG	Cytosine-phosphate-guanosine deoxynucleic acid motif
DAMP	Damage-associated molecular pattern
DC	Dendritic cell
DD	Death domain
DNA	Deoxyribonucleic acid
dsRNA	double-stranded ribonucleic acid
ER	Endoplasmic reticulum
FIIND	Function-to-find domain
GPI	Glycosylphosphatidylinositol
IFN	Type 1 interferon
IRAK	Interleukin-1 receptor-associated kinase
IRF	Interferon regulatory transcription factor
LPS	Lipopolysaccharide
LRR	Leucine-rich repeat

LTA	Lipoteichoic acid
MAMP	Microbe-associated molecular pattern
MAPK	Mitogen-activated protein kinase
MD-2	Myeloid differentiation factor 2
MyD88	Myeloid differentiation primary response gene 88
NAIPs	Neuronal apoptosis inhibitory proteins
NF- κ B	Nuclear factor-kappa B
NLR	NOD-like receptor
NACHT	NAIP class 2 transcription activator (C2TA) heterokaryon incompatibility (HET-E) and telomerase-associated protein 1 (TP1)
NOD	Nucleotide-binding and oligomerization domain
PAMP	Pathogen-associated molecular pattern
PRR	Pattern recognition receptor
PYD	Pyrine domain
RLR	Rig-I-like receptor
RNA	Ribonucleic acid
SAR	Structure activity relationship
ssDNA	Single-stranded deoxyribonucleic acid
ssRNA	Single-stranded ribonucleic acid
TAB	TAK-1 binding protein
TIR	Toll/1L-1 receptor
TIRAP	TIR domain-containing adaptor protein
TLR	Toll-like receptor
TRAF	Tumor necrosis factor receptor (TNF-R)-associated factor
TRAM	TRIF-related adaptor molecule
TRIF	TIR domain-containing adaptor inducing interferon- β

Introduction

Earth is predicted to be home to up to one trillion unique microbial species (Locey and Lennon, 2016). As such, mammals are constantly being assailed by innocuous and pathogenic bacteria, fungi, viruses, and parasites. Due to millennia of coevolution and selection of the innate and adaptive immune systems, most mammals are able to resist and overcome pathogenic infections while balancing symbiotic microbial colonization. The term “immunity” has roots in the Latin words *immunitas* and *immunis*, which in their original context in Ancient Rome referred to the legal concept of exemption. Although the concept of acquired immunity had been described several centuries earlier in China and elsewhere, it wasn’t until the late 19th century that the phrase was formalized and used commonly in the field (Silverstein, 2001). It was during this time that several scientists began providing proof of classical immunity (that is, exposure to a non-lethal antigen that results in protection from subsequent exposure with a lethal pathogen). This included Edward Jenner’s 18th century work on vaccination using the contents of cowpox pustules as a safe vaccine for smallpox and the 19th century observations of Pasteur, Koch, Ehrlich, and others for bacterial diseases (Silverstein, 2001; Willis, 1997; Smith, 2012; Blevins and Bronze, 2010; Bosch and Rosich, 2008). Despite the observed link between microbes and classical immunity, the phrase “immune system” didn’t begin appearing in journals and articles until the mid-1960s, as the field of cellular immunology began to develop. Originally, the immune system was referred to as the “lymphoid system”. The cellular reference was eventually dropped and replaced with the term immune system (Silverstein, 2001).

Early definitions of the immune system described it as a set of cells that were unbiasedly involved in all immunological reactions, with emphasis on function and not mechanism (Silverstein, 2001). In the 1970s, our understanding of the complexity of the types of cells involved in immunity began to develop, and cells began to be broken into classes: killer cells, antigen-presenting cells, helper cells, suppressor cells, etc., (Silverstein, 2001). Today, we define the immune system as the group of organs, tissues, cells, and cell products (such as cytokines and antibodies) that discriminates between self and non-self to protect the body against infection and disease and to neutralize potentially pathogenic substances (Bellavite et al., 2005; Silverstein, 2001).

Although the concept of immunology has historically been linked to microbes, it wasn’t until the late 20th century that our understanding of how our body senses individual classes of microbes began to fully develop. Charles Janeway was the first to propose the idea of host receptors that would specifically recognize microbial species, essentially laying the groundwork for what would become known as innate immunology. During his introduction to the Cold Spring Harbor Symposium in 1989, Janeway proposed that the immune system evolved to discriminate “noninfectious self from infectious non-self”, essentially stating that the immune system evolved to defend against microbes and therefore the induction of an immune response depended on microbes (Janeway, 1989). He theorized that this level of defense would be an inherent mechanism dependent on invariant receptors on innate cells, as opposed to the highly diversified and selected receptors expressed on B and T cells of the adaptive immune system.

He also proposed that these receptors would be germline-encoded and would recognize specific microbial patterns. Part of this theory was drawn from the fact that members of invertebrate kingdoms appear to lack adaptive immune systems yet are still able to respond to pathogenic stimuli (Janeway, 1989; Silverstein, 2001). Based on these and other observations, he argued that a system that identifies self from non-self must have developed early in evolutionary history and would therefore be distinct from lymphocyte-mediated immunity (Janeway, 1989).

Today, we recognize the innate immune system as the first line of defense against invading microbes, providing protection from potential infection and disease. Innate immunity is primarily mediated by antigen-presenting cells (APCs) and phagocytic cells, including macrophages, dendritic cells, and granulocytes. Unlike adaptive immunity, which is characterized by generation of specific responses and immunological memory, innate immunity is rapid and considered relatively non-specific (Silverstein, 2001). Innate immune cells rely on recognition of pathogen-specific features that are highly evolutionarily conserved. These were termed pathogen-associated molecular patterns (PAMPs) and are composed of small molecular motifs that are characteristic to classes of microbes and discriminatory from the host self. Several germline-encoded receptors termed pattern recognition receptors (PRRs) are responsible for recognizing and responding to PAMPs, matching the description previously proposed by Janeway (Janeway, 1989). In addition to PAMPs, non-pathogenic microbial species can be discriminated by the innate immune system via microbe-associated molecular patterns (MAMPs). PRRs are localized on the external cell surface, within endosomes, or in the cytosol of host immune cells and respond to specific classes of PAMPs (Kawai and Akira, 2010; Takeuchi and Akira, 2010). In certain cases, PRRs may also interpret specific host factors as 'danger' signals, known as damage-associated molecular patterns (DAMPs). These could include host molecules present in atypical locations or in abnormal molecular configurations as a result of cell stress, infection, or inflammation (Kawai and Akira, 2010; Akira et al., 2006). Upon PAMP or DAMP recognition, PRRs initiate intracellular signaling cascades that result in proinflammatory and antimicrobial responses and alert the host to the presence of the microbe. PRR signaling pathways are unique but generally result in the activation of gene expression and subsequent synthesis of a wide range of molecules such as cytokines, chemokines, and immunoreceptors. Together, these receptors and molecules orchestrate the early innate response to infection (Akira et al., 2006; Kawai and Akira, 2010). In addition to initiating inflammation and other host defense responses, PRR activation and signaling can prime and coordinate antigen-specific adaptive immune responses, providing an important link between innate and adaptive immunity. Mammals possess distinct classes of PRRs that each recognize specific molecular signatures: Toll-like receptors (TLRs), Nod-like receptors (NLRs), AIM2-like receptors (ALRs), RIG-1-like receptors (RLRs), and C-type lectin receptors (CLRs) (Kawai and Akira, 2010; Akira et al., 2006). Here, we focus on TLRs and NLRs. The other classes of receptors have been recently reviewed (Mathur et al., 2018; Shiokawa et al., 2017; Kawai and Akira, 2009). Additionally, we now appreciate the role of the immune system outside the context of microbial defense, such as in autoimmunity, though these concepts are outside the scope of this article.

Toll-like Receptors: A Historical Perspective

Of the mammalian PRRs, Toll-like receptors (TLRs) were the first to be identified and are the best characterized. TLRs are located on the cell surface or within endosomal compartments of immune cells and are crucial for host defense against microbes (Kawasaki and Kawai, 2014; Botos et al., 2011). The field of TLR research began in *Drosophila* with the identification of Toll, a protein with homology to a receptor for the inflammatory cytokine IL-1 called IL-1R type 1 (IL-1R1) (Gay and Keith, 1991). Subsequently, a plant protein (called the N protein), which conferred resistance to a Tobacco Mosaic Virus, was identified and characterized as having an amino-terminal domain similar to that of Toll and IL-1R1 (Whitham et al., 1994). This conserved domain was termed the Toll-IL-1 resistance (TIR) domain and was proposed to be involved in host defenses across disparate plant and animal kingdoms. Subsequent work by several groups, especially the Levine and Hoffmann groups, further identified downstream proteins and components linking Toll to innate immune activation in *Drosophila* (Broz and Monack, 2013; Ip et al., 1993; Steiner et al., 1981; Lemaitre et al., 1996; Rutschmann et al., 2000). However, it wasn't until 1997 that Ruslan Medzhitov, while in the Janeway laboratory, identified the first human homologue of the *Drosophila* Toll protein, termed hToll (currently TLR4) (Medzhitov et al., 1997). Upon recognition with its ligand, Medzhitov observed activation of a transcription factor called nuclear factor- κ B (NF- κ B), leading to the up-regulation of genes involved in immune and inflammatory responses. This included the gene encoding CD80, a protein involved in T-cell co-stimulation, providing a crucial observation linking the innate and adaptive immune systems (Broz and Monack, 2013; Medzhitov et al., 1997). In 1998, four mammalian Toll homologues were described in addition to TLR4. Due to the similarity between Toll and these protein homologues (all of which contained conserved TIR domains), the proteins were termed Toll-like receptors (TLRs), a name which has since been adopted as standard nomenclature (Broz and Monack, 2013; Rock et al., 1998).

Research to identify the ligands recognized by individual TLRs focused on microbial products suspected to be involved with innate immune responses based on the previous studies in *Drosophila* (Broz and Monack, 2013). The initial search for PRR ligands focused largely on lipopolysaccharide (LPS), a major component of the outer leaflet of the outer membrane of Gram-negative bacteria. LPS was known to activate NF- κ B and was therefore an obvious potential PAMP. Prior to the discovery of TLR4, the genetic basis for LPS recognition was identified in mice that had acquired a spontaneous mutation that conferred resistance to LPS toxicity (C3H/HeJ mice) (Heppner and Weiss, 1965; Sultz, 1968). LPS resistance was mapped to a single autosomal gene named *Lps^d* (Qureshi et al., 1999; Watson et al., 1978; Coutinho and Meo, 1978). Subsequent to the discovery of TLR4, studies by Yang and colleagues showed that expression of a yet-unknown TLR made cells responsive to LPS preparations, providing evidence that TLRs were in fact PRRs (Yang et al., 1998). Initially, the LPS receptor was mis-identified as TLR2 due to high levels of contaminating

lipoproteins (which are potent activators of TLR2) in the experimental LPS preparations (Hirschfeld et al., 2000). However, positional cloning work by Bruce Beutler's group identified *Tlr4* as the genetic component responsible for LPS sensing and response (Poltorak et al., 1998). Subsequent work from the Malo and Akira groups also confirming that TLR4 is the signaling receptor for LPS, thereby showing that *Tlr4* was in fact *Lps^d* (Qureshi et al., 1999; Takeuchi et al., 1999). By 2007, ten human TLRs and twelve murine TLRs had been identified (hToll was renamed TLR4) (Beutler, 2008). Work to characterize TLR ligands and modes of recognition is still ongoing. Knockout mouse lines, largely generated by Akira and colleagues, TLR crystal structures, and a better understanding of the structure of the lipid A component of LPS have been important resources for characterization of TLR sensing and signaling.

TLR Structure & Synthesis

Structurally, TLRs are type I integral transmembrane glycoproteins that possess an N-terminal ectodomain, a single transmembrane α -helix, and a C-terminal intracellular signaling domain, each of which are essential for its function (Botos et al., 2011; Beutler, 2008). The ectodomain is responsible for binding the associated PAMP and is characterized by a motif of leucine-rich repeats (LRRs), the number of which vary by TLR, and characteristic structures capping the N- and C-terminus (Fig. 1(A)). Also called the extracellular domain, this region is generally 550–800 amino acids in length, variably glycosylated, and exposed either on the cell surface or within endosomes (Wang et al., 2016; Botos et al., 2011). Crystal structures of human or murine TLR ectodomains report a horseshoe shape with PAMPs binding on the inner curvature of the horseshoe and ligand-induced dimerization occurring on the latter face of the receptor (Fig. 1(B); Jin et al., 2007; Kang et al., 2009; Liu et al., 2008; Park et al., 2009). The helical transmembrane domain typically contains a stretch of ~ 20 uncharged, mostly hydrophobic amino acids that integrate the receptor into the endosomal or plasma membrane. The intracellular signaling domain contains the ~ 200 amino acid TIR domain (Wang et al., 2016; Liu et al., 2008).

TLRs are synthesized in the endoplasmic reticulum and trafficked to the Golgi apparatus, where they are sorted and recruited to the cell surface or endosomal compartments (Kawasaki and Kawai, 2014). Proper intracellular localization of TLRs is critical for ligand recognition and prevention of autoimmunity, which could result from TLRs coming into contact with self-nucleic acids (Kawasaki and Kawai, 2014). In mammals, the transmembrane protein UNC93B1 controls intracellular trafficking from the ER to endosomes via interaction between its transmembrane region and the TLR transmembrane helix (Kim et al., 2008; Tabeta et al., 2006). TLRs that do not interact with UNC93B1 are trafficked directly to the cell surface (Botos et al., 2011; Kawasaki and Kawai, 2014). PRAT4A, an ER-resident protein, is also crucial for trafficking of TLR1, 2, 4, 7, and 9 (Takahashi et al., 2007). The heat-shock-related ER-resident protein gp96 serves as a general chaperone molecule for most TLRs, including intracellular TLR7

Fig. 1 TLR Structure. (A) Toll-like receptors are composed of leucine-rich repeats (LRRs), which vary in number based on the specific TLR. The LRRs are capped by characteristic structures and are connected to an intracellular TIR signaling domain via a transmembrane α -helix. (B) The TLR ectodomain, composed mainly of LRRs, forms a horseshoe-like shape, with PAMP ligands binding on the internal concave face. Ectodomains interact to form hetero- or homo-dimers, depending on the TLR. An α -helical transmembrane domain links the ectodomain to the intracellular, conserved TIR signaling domain.

and 9 and cell-surface-associated TLR1, 2, 4, and 5 (Yang et al., 2007). Endosomal-associated TLRs undergo specific proteolytic cleavage once they arrive in the endosome to produce the functional receptor capable of ligand recognition and signal initiation (Park et al., 2008; Ewald et al., 2011; Garcia-Cattaneo et al., 2012).

During PRR ligand studies and structural characterization, several co-receptors have been identified that are important for TLR function and activity. This includes myeloid differentiation factor 2 (MD-2), a 160 amino acid soluble protein that is glycosylated and binds to the concave, extracellular face of TLR4. MD-2 is required for recognition of LPS and therefore subsequent TLR4 function (Shimazu et al., 1999; Schromm et al., 2001; Park et al., 2009). Additional co-receptors are cluster of differentiation 14 (CD14) and cluster of differentiation 36 (CD36). CD14 is a glycoprotein of 375 amino acids that is found either soluble in the blood or linked to the membrane of myeloid cells via a glycosylphosphatidylinositol (GPI)-anchor and contributes to TLR2 and TLR4 ligand recognition (Zanoni et al., 2011; Baumann et al., 2010). Specifically, CD14 has been shown to bind LPS and deliver it into the TLR4/MD-2 complex. It can additionally extract LPS monomers from LPS-binding protein (LBP), which is a soluble protein that interacts with intact bacteria or LPS aggregates in the extracellular space (Kagan et al., 2008; Triantafilou and Triantafilou, 2002). CD36 has been shown to contribute to TLR2, TLR6, and TLR4 activation (Stewart et al., 2010; Sheedy et al., 2013). Models suggest that CD36 binds negatively charged lipo-ligands and transfers them to CD14, which then loads them into their respective TLRs. This has been proposed for ligands such as lipoteichoic acid (LTA, sensed by TLR2/6) and mycobacterial lipomannan (sensed by TLR1/2) (Jiménez-Dalmaroni et al., 2009).

TLRs are not analogous between systems, including across or within mammalian groups, as evidenced by the fact that humans possess ten TLRs (TLR1-TLR10) and mice possess twelve (TLR1-TLR9, TLR11-TLR13) (Kawasaki and Kawai, 2014). The TLR multigene family is composed of a variable number of genes that are species-specific (generally between 10 and 15 per species). However, comparative studies have shown that the TIR domains of TLRs are highly conserved across species, which is unsurprising due to their crucial role in signal transduction (Werling et al., 2009; Roach et al., 2005). Although all TLRs share the same common structural architecture, the specific TLRs that are present, what they recognize, and how they respond varies by species. The ectodomains, and specifically the face involved in ligand recognition, exhibit the highest level of variation between species, indicative of their function in recognizing PAMPs from multiple sources that are influenced by the microbial environment a particular species occupies (Werling et al., 2009). In some cases, homologous TLRs across species are proposed to have functional differences in what they sense. For example, bovine TLR1/TLR2 and chicken TLR2 type 2/TLR16, respond to both tri- and di-acylated peptides, whereas in other mammals, including mice and humans, these ligands are independently sensed by TLR1/2 and TLR2/6, respectively (Farhat et al., 2008). Additionally, homologous receptors across species may respond differently to the same ligand. This is the case for TLR4, in which specific *Pseudomonas aeruginosa* LPS structures differentially drive signaling in murine TLR4 versus human TLR4 and LPS from *Rhodobacter sphaeroides* is agonistic to TLR4 in horses and hamsters but antagonistic in humans and mice (Hajjar et al., 2002; Lien et al., 2000; Lohmann et al., 2007). LPS from some species, such as *E. coli*, activates TLR4 in a host-species-independent manner, while others, like that from *Salmonella enterica*, are recognized in a host-species-dependent manner (Hajjar et al., 2012; Lien et al., 2000; Lohmann et al., 2007; Werling et al., 2009). These inconsistencies are presumed to be due to differences in the variable regions in the TLR4 ectodomain and possibly differential associations of MD-2 with TLR4 (Werling et al., 2009; Hajjar et al., 2012).

The TLR Signaling Axes

TLR signaling is initiated upon binding and recognition of unique signature molecules, which are specific to the TLR (Table 1). Intracellular adaptor molecules are recruited to the TLR via the conserved and essential cytoplasmic TIR domain (Fig. 2; Werling et al., 2009; Kawasaki and Kawai, 2014). Cytoplasmic adaptor proteins involved in TLR signaling contain complementary TIR domains and include Myeloid differentiation primary response gene 88 (MyD88), TIR domain containing adaptor protein (TIRAP, also known as MyD88-adaptor-like or Mal), TIR-domain-containing adaptor-inducing interferon- β (TRIF), and TRIF-related adaptor molecule (TRAM). Specific adaptors are differentially recruited to the TLRs after activation and influence the robustness of the signaling cascade (Werling et al., 2009; Kawasaki and Kawai, 2014).

TLR signaling can occur via two axes, mediated by MyD88 (the MyD88-dependent pathway) or TRIF (the MyD88-independent or TRIF pathway) (Fig. 2). The majority of TLRs signal exclusively through the MyD88-dependent pathway, with the exception of TLR3 which signals through the TRIF pathway and TLR4, which can signal through both pathways (Kawasaki and Kawai, 2014; Jiménez-Dalmaroni et al., 2016). Signaling is proposed to be initiated via conformational changes in the TLR ectodomain after ligand binding that bring the intracellular TIR domains in close proximity and allows for the recruitment of TIR-containing adaptor proteins. Additional adaptor proteins are required to facilitate signaling. TIRAP/Mal mediates interactions between MyD88 and TLR2, TLR4, and, in some cases, TLR9. TLR4 also requires an adaptor protein called TRAM when interacting with TRIF in the MyD88-independent signaling pathway (Kawasaki and Kawai, 2014; Jiménez-Dalmaroni et al., 2016).

After TLR activation, MyD88-depending signaling is initiated by the formation of the 'Myddosome' complex between MyD88, IRAK1, and IRAK4. IRAK4 activates IRAK1, which autophosphorylates at several sites and is released from the Myddosome (Kollewe et al., 2004; Jiang et al., 2002). IRAK1 then associates with TRAF6, a RING-domain E3 ubiquitin ligase, which acts in coordination with ubiquitin-conjugating enzyme UBC13 and UEV1A to polyubiquitinate the K63 residue of TRAF6 and the TAK1 protein kinase complex (Chen, 2012; Ajibade et al., 2013). TAK1 subsequently activates the IKK complex, composed of catalytic subunits IKK α and IKK β and regulatory subunit NEMO (sometimes referred to as IKK γ). The activated IKK complex phosphorylates I κ B α , the NF- κ B inhibitory protein. Phosphorylated I κ B α is degraded, freeing NF- κ B to translocate to the nucleus and induce expression of pro-

Table 1 TLR localization and their associated PAMPs in human and mice

TLR – human	TLR – mouse	Location	PAMP recognized
1	1	Cell surface	See TLR2
2	2	Cell surface	Glycolipids, peptidoglycans, LTA, bacterial triacylated lipopeptides (TLR1/2) and diacylated lipopeptides (TLR2/6) (Kawai and Akira, 2010; Takeuchi et al., 1999; Dziarski and Gupta, 2000)
3	3	Endosome	Viral dsRNA, siRNA, self-RNAs from damaged cells (Zhang et al., 2007; Bernard et al., 2012; Takemura et al., 2014)
4	4	Cell surface/endosome	Lipopolysaccharide (LPS)(Takeuchi et al., 1999; Dziarski and Gupta, 2000); mannuronic acid polymers, teichuronic acid, and viral proteins (Vaure and Liu, 2014)
5	5	Cell surface	Flagellin (Hayashi et al., 2001; Ramos et al., 2004)
6	6	Cell surface	See TLR2
7	7	Endosome	ssRNA from viruses, RNA from streptococcus B bacteria (cell-type specific) (Mancuso et al., 2009; Crozat and Beutler, 2004)
8	8	Endosome	Viral & bacterial RNA (Guiducci et al., 2013)
9	9	Endosome	Bacterial & viral DNA rich in unmethylated CpG-DNA motifs; heozoin (from <i>Plasmodium</i> infection) (Coban et al., 2010)
10	Pseudogene	Cell surface	<i>Listeria</i> ligands (TLR2/10), influenza A virus infection ligands (Regan et al., 2013; Lee et al., 2014)
Pseudogene	11	Endosome	Flagellin; components from <i>E. coli</i> UPEC and <i>Toxoplasma gondii</i> (Mathur et al., 2012; Yarovinsky et al., 2005); see also TLR12
None	12	Endosome	Homodimer or heterodimer with TLR11; profilin from <i>T. gondii</i> (Andrade et al., 2013; Koblansky et al., 2013; Broz and Monack, 2013)
None	13	Endosome	Bacterial 23S rRNA, vesicular stomatitis virus (Hidmark et al., 2012; Li and Chen, 2012; Oldenburg et al., 2012; Shi et al., 2011)

Fig. 2 TLR signaling. Ligand binding to a TLR is proposed to induce conformational changes that initiate intracellular signaling cascades. The specific signaling cascade and robustness of the response is influenced by the ligand, TLR, and adaptor molecules. Signaling can occur on the MyD88-dependent axis or the MyD88-independent/TRIF axis, with characteristic proteins involved in both pathways. The end result of both cascades is translocation of transcription factors into the nucleus, leading to up-regulation of specific genes that will aid in the host response to the initial microbial stimuli.

inflammatory genes. TAK1 activation additionally leads to activation of proteins in the MAPK family such as ERK1/2, JNK, and p38. This in turn activates transcription factors belonging to the AP-1 family or that are involved in regulation of the inflammatory response through stabilization of mRNAs (Kawasaki and Kawai, 2014; Akira et al., 2006; Takeuchi and Akira, 2010).

The second signaling axis is TRIF-dependent. Upon TLR activation, TRIF is recruited and interacts with TRAF3 and TRAF6. TRAF3 activation leads to recruitment of IKK-related kinases TBK1 and IKKi, in addition to the regulatory protein NEMO, resulting in phosphorylation of IRF3 (Kawasaki and Kawai, 2014; Akira et al., 2006; Takeuchi and Akira, 2010). Phosphorylated IRF3 forms a homodimer and translocates from the cytoplasm into the nucleus, where it promotes expression of type I IFN genes. Conversely, TRAF6 activation leads to the recruitment of the RIP-1 kinase, which recruits and activates the TAK1 complex. As with the MyD88-dependent pathway, TAK1 complex activation leads to activation of MAPKs and NF- κ B and production of inflammatory cytokines (Kawasaki and Kawai, 2014; Akira et al., 2006; Takeuchi and Akira, 2010).

Surface-Associated TLRs

TLRs can be broadly categorized based on their cellular localization, either on the cell surface or within endosomes. It's important to note that TLRs do not remain static. Surface-expressed TLRs, such as TLR4, have been described to transit to the endosome and in some cases, endosomal TLRs may transit to the cell surface (Beutler, 2008). Cell surface-associated TLRs primarily recognize PAMPs that would be present outside of the host cell as a consequence of extracellular infection, such as microbial membrane components. Most TLRs function as homodimers, although some function as heterodimers, as is the case for TLR2 (Akira et al., 2006; Takeuchi and Akira, 2010). TLR2 recognizes the broadest range of PAMPs due to its heterodimerization with other TLRs, including TLR1, 6, and 10. TLR2 PAMPs include lipoproteins, peptidoglycans, lipoteichoic acid from Gram-positive bacteria, zymoxan, tGPI-mucin, and mannan (Table 1; Kawasaki and Kawai, 2014; Chandler and Ernst, 2017). Specifically, TLR1/2 recognizes triacylated lipoproteins (predominantly from Gram-negative bacteria) and TLR2/6 recognizes diacylated lipoproteins (predominantly from Gram-positive bacteria) (Chandler and Ernst, 2017; Kirschning and Schumann, 2002). While much research has been done to identify ligands sensed by TLR2, the second TLR partner required for such recognition is less well understood and is still an active area of research. TLR5 recognizes flagellum, which are protein-based appendages extruding from microbial cells that aid in movement, and has been specifically described to respond to flagellum of pathogenic invasive bacteria in the intestinal epithelium (Hayashi et al., 2001; Ramos et al., 2004). TLR10 can sense influenza A virus infection in humans through an unknown mechanism and can pair with TLR3 to recognize specific extracellular ligands during listeria infection (Regan et al., 2013; Lee et al., 2014). In mice, TLR10 exists as a non-functional pseudogene (Roach et al., 2005).

TLR4 is perhaps the most well-studied TLR and primarily recognizes lipopolysaccharide (also known as endotoxin) from Gram-negative bacteria. Crystal structures of TLR4/MD-2 in complex with LPS suggest that up to five LPS acyl chains bind in a hydrophobic pocket in MD-2 with the sixth interacting with a hydrophobic patch on TLR4 itself (Park et al., 2009; Kim et al., 2007). Homodimers of TLR4/MD-2 recognize the lipid A portion of LPS in a structure-dependent manner and efficacy of recognition is variable between human and mouse cell lines (Scott et al., 2017; Hajjar et al., 2012). TLR4 has also been described to recognize mannuronic acid polymers, teichuronic acid, and viral proteins (Table 1; Vaure and Liu, 2014). TLR4 is unique because it can signal from the cell surface (through the MyD88-dependent pathway) and subsequently from endosomes (through the TRIF pathway) (Fig. 2). After ligand recognition and TLR4/MD-2 dimerization, TLR4 is endocytosed in a CD14-dependent manner. This process is termed 'inflammatory endocytosis' and is regulated by unique adaptors, GTPases, and calcium. Recent studies revealed that MD-2 is the key component allowing TLR4 to be selected for endocytosis by CD14 and previous work has shown that CD14 alone, but not TLR4 alone can be endocytosed in the presence of LPS. Endocytosis of TLR4 and subsequent TRIF signaling has also been observed to be differential between unique cell types (Kagan et al., 2008; Tan et al., 2015; Rajaiah et al., 2015).

Endosomal

Endosomal TLRs largely recognize microbial products that result from intracellular infection or that are taken into the cell via endocytosis, including bacterial- and viral-derived nucleic acids, in addition to self-nucleic acids in certain autoimmune disease conditions (Kawai and Akira, 2010; Kawasaki and Kawai, 2014). As obligate intracellular microbes, viruses are almost exclusively sensed by endosomal TLRs, with specific TLRs differentially sensing different viral classes. TLR3 senses double-stranded viral RNA (dsRNA, formed during the replication process of positive-strand RNA viruses), small interfering RNA (siRNA), and self-RNA produced from damaged host cells (Kawai and Akira, 2010; Kawasaki and Kawai, 2014). Crystal structures revealed that the phosphate backbone of the dsRNA, not the nitrogenous bases, are the feature recognized by TLR3 and that recognition involves the ectodomain LRR motif (Liu et al., 2008; Choe et al., 2005). TLR3 also has roles in the pathogenesis of influenza virus and encephalitis caused by West Nile virus and herpes simplex virus (Zhang et al., 2007; Bernard et al., 2012; Takemura et al., 2014). Endosomal TLRs may recognize both viral and bacterial-derived nucleic acid, as is the case for TLR7 and TLR8. Both form homodimers that primarily recognize viral-specific single stranded RNA (ssRNA), but can additionally recognize some bacterial RNA (Kawai and Akira, 2010; Kawasaki and Kawai, 2014). TLR7 is primarily expressed in plasmacytoid dendritic cells (pDCs) where it senses ssRNA, but when expressed in conventional dendritic cells (cDCs) it can recognize RNA from streptococcus B bacteria (Mancuso et al., 2009; Crozat and Beutler, 2004). In humans, TLR8 recognizes viral and bacterial RNA (Guiducci et al., 2013). Structural analysis of TLR8 suggests that it exists as a preformed dimer, which changes conformation upon ligand recognition and binding (Tanji et al., 2013). TLR9 recognizes DNA that is rich in unmethylated CpG-DNA motifs, which could be bacterial or viral in

origin and is notably distinct from 'self' nucleic acid. TLR9 has also been proposed to recognize a byproduct produced during *Plasmodium falciparum* infection called hemozoin (Coban et al., 2010).

Mice possess three TLRs that are not present in humans – TLR11, TLR12, and TLR13. TLR11 recognizes a component of uropathogenic *Escherichia coli* (UPEC; possible flagellin or a proteinaceous component) and profilin-like molecules originating from *Toxoplasma gondii* (Mathur et al., 2012; Yarovinsky et al., 2005). TLR12 is similar to TLR11 and is mostly expressed in myeloid cells where it senses profilin from *T. gondii*. TLR12 may function as a homodimer or a heterodimer with TLR11 (Koblansky et al., 2013; Andrade et al., 2013; Broz and Monack, 2013). TLR13 senses bacterial 23S rRNA and components of the vesicular stomatitis virus that have yet to be determined (Oldenburg et al., 2012; Hidmark et al., 2012; Shi et al., 2011).

Nod-Like Receptors: Cytosolic PRRs

Although TLRs were the first PRRs to be described, our knowledge about additional innate immune receptors has rapidly expanded in the past decade. Nucleotide-binding and oligomerization domain (NOD)-like receptors (NLRs) were first identified in plants where they were described to function in disease resistance against microbial pathogens (leading them to be called *R* genes) (Ogura et al., 2001; Chamaillard et al., 2003). As genome sequencing became more accessible, homologues of plant NLRs were subsequently identified in vertebrates and other organisms, including primitive organisms such as sea urchin (Shaw et al., 2008; Girardin et al., 2003). Today, we understand NLRs to be evolutionarily conserved soluble innate immune receptors that, like TLRs, serve as PRRs. Additionally, TLRs and NLRs can act synergistically or independently to promote stimuli-dependent innate immune responses (Kufner and Sansonetti, 2007; Shaw et al., 2008).

NLRs are multi-domain proteins with three conserved regions: a variable N-terminal effector domain; a central NOD (or NACHT) nucleotide-binding domain; and a C-terminal domain composed of a series of leucine rich repeats (LLRs) (Fig. 3(A)). NLRs are found in the cytosol and are therefore primarily responsible for surveying the intracellular environment (Stam et al., 2016; Yuen et al., 2014; Buckley and Rast, 2015; Wu et al., 2017b; Howe et al., 2016). Microbes capable of evading extracellular immunity and entering the cell across the plasma membrane or through escape from a phagosome should consequentially be detected by the cytosolic NLRs. Upon activation, the variable N-terminal domain interacts with downstream factors to initiate signaling cascades that result in inflammasome assembly, transcriptional activity, regulation of inflammatory responses, and pyroptosis. The distinct biological outcome of NLR activation is dependent on the N-terminal domain. As such, the NLRs are divided into four subfamilies based on their N-terminal domain: NLRP, NLRC, NLRA, and NLRB (Wilmanski et al., 2007). Humans possess 23 NLR family members, while mice have at least 34 NLR genes (Kufner and Sansonetti, 2007; Shaw et al., 2008).

NLR Signaling & the Inflammasome

In the absence of PAMP or DAMP signals, NLRs exist in the cytosol as auto-inhibited monomers (Fig. 3(B)). NLRs are capable of recognizing and binding specific PAMP/DAMPs through their C-terminal LRR domain, resulting in a conformational change that exposes the central NOD domain. Once exposed, the NOD domains of similar NLRs oligomerize and initiate the recruitment of accessory signaling proteins capable of propagating a wide range of responses. This most notably includes activation of the inflammasome and the MAPK signaling cascade (Zhong et al., 2013).

Fig. 3 NLR Structure. (A) NOD-like receptors each contain a NOD domain as well as different combinations of signaling domains, and leucine-rich repeats (LRRs). (B) An inflammasome (NLRC4 pictured) is formed when the LRR of an inflammasome NLR is bound by a microbial ligand (black starburst). Ligand binding causes the conformation of the protein to be altered so that there is a 90-degree angle between the NOD and LRR. This allows for circular oligomerization and brings the CARD domains, on either the NLR itself or inflammasome adaptor proteins, into close proximity. The CARD domains are then capable of activating caspase-1 and so initiation inflammasome-associated inflammation.

The inflammasome, candidly referred to as a 'wheel of death', is defined as a cytosolic oligomer of proteins that initiates the activation of caspase-1, subsequently leading to the release of pro-inflammatory mediators, including IL-1 β and IL-18 (Martinon et al., 2002). Upon ligand binding, inflammasome formation commences with the oligomerization of the individual NLRs, which subsequently brings the N-terminal pyrin domains (PYDs) into close proximity with each other. Assembly of PYD recruits the apoptosis-associated speck-like protein (ASC), an adaptor protein that contains both a PYD and caspase-activating and recruitment domain (CARD) (Srinivasula et al., 2002). NLRs that contain a CARD domain, most notably the NLRC family and NLRP1, do not require ASC or other accessory scaffolding proteins (Fig. 3(A)). After oligomerization and ASC recruitment (if required), the CARD portion of pro-caspase-1 associates with the assembled CARD domains in the middle of the inflammasome. Pro-caspase-1 is then cleaved and activated caspase-1 is released from the signaling complex. Active caspase-1 subsequently cleaves zymogens of the pro-inflammatory IL-1 family of cytokines yielding bioactive IL-1 β and IL-18, which can then be secreted (Fig. 4). Caspase-1 activation can ultimately lead to a specific form of cell death termed pyroptosis. Although the exact molecular mechanism that mediate caspase-1-dependent pyroptosis are not fully understood, studies have suggested that active caspase-1 monomers assemble in the plasma membrane forming a pore through which intracellular components are released into the environment (Ting et al., 2008). In addition to responding to intracellular pathogens, inflammasomes are necessary for the ordered destruction of tissue during fetal development and homeostatic cell death at environmental interfaces. Currently, the human NLR proteins that have been shown to form inflammasomes are NAIP, NLRP1, NLRP3, NLRP6, NLRP7, NLRP12, and NLRC4 (Pétrilli et al., 2007). Inflammasomes are classified by the type of NLR they are composed of, resulting in three dominant types: NLRP3 inflammasome (also called NALP3), NLRP1 inflammasome (also called NALP1), and the NLRC4 inflammasome (also called IPAF) (Shaw et al., 2008).

NLRP Subfamily

The NLRP subfamily is characterized by the presence of a N-terminal pyrin domain (PYD), in addition to the NOD and LRR domains (Fig. 3(A)). The presence of a PYD means that this subfamily of cytosolic innate receptors can recruit ASC and other inflammasome-activating scaffold proteins, leading to strongly pro-inflammatory pyroptotic cell death. Humans possess fourteen NLRP proteins (Chavarría-Smith and Vance, 2015).

Fig. 4 NLR signaling. Transcription and translation of NLR proteins require activation of a 'signal one', most commonly through an extracellular TLR and/or TNF receptor. Once translated and transported to the cytosol, NLRs are activated by microbial ligands which bind to the LRR. Activated NLRs oligomerize form an inflammasome, initiate pro-inflammatory signaling, or regulate inflammatory pathways.

NLRP1 was the first protein described to lead to inflammasome formation, although at the time its activators were unknown. Subsequent research has shown that activators of NLRP1 include *Bacillus anthracis* lethal toxin, *Toxoplasma gondii*, muramyl dipeptide, and rapid ATP depletion (Ewald et al., 2014; Moayeri et al., 2012). In addition to PYD, NOD, and LRR, NLRP1 also contains a function-to-find domain (FIND) and a CARD domain, which enables it to recruit effector caspases without the requirement of an adaptor protein (Hiller et al., 2003). In mice, three NLRP1 paralogs have been identified: NLRP1a, NLRP1b, and NLRP1c. Interestingly, these proteins do not contain a PYD and high levels of expression have been linked to resistance to bacterial toxins (Sastalla et al., 2013).

NLRP2-9 and 11-14 all contain a PYD, NOD, LRR, and a small unique functional region that distinguishes them from each other (Fig. 3(A)). Although this category of NLRPs has similar functional domain organization, the resulting protein functions vary widely. Of these, NLRP3 is the most widely studied. NLRP3 is a strong negative regulator of pro-inflammatory signaling and is highly expressed in macrophages, forming an ASC-dependent pyroptosis-inducing inflammasome upon activation. Known NLRP3 inflammasome activators are components of cellular damage and dysregulated metabolic processes including extracellular ATP, potassium flux, reactive oxygen species, and crystalline uric acid (Stehlik and Reed, 2004). Traditional bacterial ligands have not been identified, although metabolic byproducts from bacterial growth or cell wall lysis are capable of activating the NLRP3 inflammasome (Martinon et al., 2004). The NLRP6 inflammasome, while less studied than NLRP3, is also activated by host and bacterial metabolites, but has been shown to be expressed at high levels in more specialized tissues. This includes the gut epithelia where it is thought to contribute to homeostatic cell death and tissue regeneration (Elinav et al., 2011; Anand et al., 2012; Chen et al., 2011).

NLRP2 is a regulator of NF- κ B signaling and its functional expression is necessary for fertility, healthy maternal/fetal relationships, and embryo development (Fontalba et al., 2007). NLRP4 is also a negative regulator of immune signaling, thought to be involved in healthy fetal development and has been shown to directly interact with several infection-induced signaling molecules including TBK1 (involved in interferon production) and beclin1 (involved in autophagy) (Charoenthongtrakul et al., 2012; Jounai et al., 2011; Tian et al., 2009). Similarly, NLRP11 is found to regulate innate immune signaling by directly targeting the pro-inflammatory mediators TRAF6 (involved in TLR signaling) and MAVS (involved in interferon production) (Wu et al., 2017a; Qin et al., 2017). NLRP8, NLRP9, NLRP13, and NLRP14 have not been as widely investigated, but studies have shown that they have increased expression in reproductive tissue of mammals (Monk et al., 2017).

NLRP7 and NLRP12 form inflammasomes that are found to be activated in very specific instances of pathogenesis, as well as during fetal development as a means of tissue regulation (Murdoch et al., 2006). *Staphylococcus aureus*, *Listeria monocytogenes*, and bacterial acylated lipoproteins have been reported to activate the NLRP7 inflammasome (Radian et al., 2013). Aberrant signaling of NLRP7 has been associated with high incidences of inflammatory bowel disease, ulcerative colitis, chronic obstructive pulmonary disease (COPD), and recurrent pregnancy loss (Huang et al., 2013; Onoufriadis et al., 2018). NLRP12 is found to form inflammasomes when exposed to bacterial components from many species including *Yersinia pestis*, *Micobacterium tuberculosis*, and *Klebsiella pneumoniae* (Vladimer et al., 2012; Allen et al., 2013).

Additionally, it has been associated with murine neutrophil recruitment and maybe involved in regulation of the gut microbiota through the promotion of beneficial commensals (Hornick et al., 2018; Allen et al., 2012). Although specific mechanisms have not been elucidated, NLRP12 is classically described as a negative regulator of inflammatory signaling in immune cells (Arthur et al., 2010).

NLRP10 is unique because it is the only member of the NLRP subfamily that does not contain a LRR domain, yet still retains the characteristic PYD and NOD domains. NLRP10 is highly expressed in the epidermis of both mouse and human skin and contributes to the regulation of immune activation in the presence of commensals (Lachner et al., 2017). Furthermore, it is described as a negative regulator of ASC-dependent inflammasome signaling by inhibiting maturation of caspase-1 and IL-1 β . Although the exact mechanism of inhibition has not been elucidated, it is thought that NLRP10 may interact with the PYD domain on the inflammasome scaffolding protein ASC. A role for the induction of adaptive immunity through dendritic cell migration and involvement in the NOD-1 signaling cascade have also been proposed for this unique NLRP protein (Eisenbarth et al., 2012; Lautz et al., 2012).

NLRC Subfamily

The NLRC subfamily of NLRs is characterized by the presence of an N-terminal CARD domain followed by the classic NOD and LRR domains (Fig. 3(A)). NOD1 and NOD2 are included in this category and are classic cytosolic PRRs responsible for responding to bacterial peptidoglycan fragments, DAMPs, and disturbances in homeostatic cellular processes, including actin cytoskeleton and endoplasmic reticulum formation (Keestra-Gounder and Tsois, 2017; Byndloss et al., 2016). NOD1 is activated by the Gram-negative bacterial product γ -D-glutamyl-mesodiaminopimelic acid (iE-DAP), while NOD2 is activated by muramyl dipeptide (MDP) present in both Gram-positive and Gram-negative bacteria. Additionally, viral particles have been described to activate both NOD1 and NOD2. NOD1 has an N-terminal CARD domain, followed by a NOD and LRR, whereas NOD2 has two N-terminal CARD domains. Despite the presence of CARD domains, activated NOD1 and NOD2 do not result in the formation of an inflammasome. Instead, they self-oligomerize after ligand stimulation and recruit an adaptor protein that activates TAK1. As in the TLR-signaling pathway, TAK1 subsequently activates NF- κ B and MAPK signaling cascades, resulting in transcription factor translocation into the nucleus and up-regulation of pro-inflammatory mediators (Fig. 4; Kawai and Akira, 2009). Although these NLRC proteins do not directly result in pyroptotic cell death, they have both been found to contribute to activating autophagic processes through the pro-inflammatory signals they initiate (Kaparakis-Liaskos, 2015). As with all pro-inflammatory processes, unregulated NOD signaling

can lead to the formation of chronic inflammation syndromes. Strong evidence is emerging that genetic differences in the NOD2 protein are linked with the development of Crohn's disease (Caruso et al., 2014). Similar to NOD1, the NLRC4 inflammasome contains a CARD domain though its activation is ASC-independent. NLRC4 signaling is activated by bacterial flagellin and components of the type-3-secretion systems and results in the recruitment of caspase-1, which initiates inflammation and pyroptosis as previously described.

NLRC3, NLRX1, and NLRC5 all have unusual N-terminal signaling domains and therefore very different functions than the aforementioned NLR family members. NLRC3 contains a CARD domain that does not activate caspase-1 and functions to negatively regulate inflammatory signaling pathways. This includes pathways induced by STING (a sensor of DNA) and NF- κ B-activated signaling pathways (Allen, 2014; Zhang et al., 2014). NLRX1 contains an N-terminal mitochondrial localization signal and similarity negatively regulates the host immune response to viral infection by promoting autophagy. Once activated, it is capable of directly binding the IKK complex to inhibit NF κ B signaling or can interfere with the cytosolic Rig-I receptor, which dampens interferon responses to viral infection. NLRC5 contains a death domain at the N-terminus and has been shown to regulate components for the development of adaptive immunity, specifically MHC-I driven immunity, while dampening pro-inflammatory signaling (Benko et al., 2010). This NLR is found to be a strong trans-activator of the MHC-I locus, resulting in the recruitment of transcription factors to the MHC-I promoter region and allowing for increased expression of not only MHC-I, but also the proteins required to facilitate antigen presentation in the context of MHC-I (Kobayashi and van den Elsen, 2012; Neerinx et al., 2013; Meissner et al., 2012).

NLRA and NLRB

The NLRA subfamily is characterized by an N-terminal acidic transactivation domain (Fig. 3(A)) and contains only one known member: Class II major histocompatibility transactivator (CIITA). CIITA works as a trans-activator of MHC class II immunity by interacting with three main transcription factors (RFX5, NF-Y, and CREB) to promote the transcription of MHC II and related genes (Zika et al., 2003; Devaiah and Singer, 2013). CIITA tightly regulates MHC production through its combined acyltransferase and kinase activity. Mutations in CIITA have been linked with aberrant MHC expression-associated autoimmunity.

The NLRB subfamily includes the neuronal apoptosis inhibitory proteins (NAIPs), which possess LRR and NOD domains followed by three N-terminal baculoviral inhibitory repeat-like domains (BIR) (Fig. 3(A)). NAIPs have been shown to directly interact with bacterial PAMPs. In humans, there is a single expressed NAIP that is capable of detecting both bacterial type-3 secretion system and flagellum, whereas mice have seven paralogs of the human receptor that share similar ligands. Mouse NAIP1 and NAIP2 recognize components of the bacterial type-3 secretion system, and mouse NAIP5 and NAIP6 recognize flagellum. Subsequent to encountering PAMPs, these complexes interact with and activate the NLRP4 inflammasome, leading to caspase-1 activation and pyroptotic cell death (Reyes Ruiz et al., 2017; Zhao and Shao, 2015; Chavarría-Smith and Vance, 2015).

Perspectives

Due to their role in innate immunity, TLRs and NLRs are critical components for the early defense against pathogens and subsequent induction of adaptive immunity. As such, regulation of their expression and signaling is complex. Functional abnormalities of TLRs, NLRs, or their associated co-receptor and/or signaling molecules have been implicated in diseases ranging from autoimmunity to cancer and are worthy of a separate article. With improvements in characterization of PRR ligands and signaling mechanisms, our understanding of host defenses and disease has also developed. However, the minimal structural requirements leading to PRR activation and signaling still remains an active and needed area of research. In addition to initiating early responses to infection, signaling cascades initiated by these receptors induce key factors that link the innate and adaptive immune systems. Specifically, critical studies on receptor-ligand interactions and structure-activity relationships will help advance our understanding of microbial recognition and could pave the way for therapeutic development.

Glossary

Cell envelope Is the set of layers that delimit and wrap a bacterial cell, normally composed by the cytoplasmic membrane and cell wall (sacculus) plus an outer membrane in Gram-negative bacteria.

Muropeptide Each of the monomeric subunits of peptidoglycan.

Peptidoglycan Is a polymer consisting of sugars and amino acids. Murein (from the latin *murus*, meaning wall) is the particular form found in the bacterial cell walls; however, the generic term is most often used. Some Archaea present structurally similar components named pseudomurein.

Periplasm or periplasmic space Is the compartment between the cytoplasmic membrane and the outer membrane in Gram-negative bacteria.

Sacculus Also known as the cell wall, is the rigid layer of the bacterial cell envelope made of peptidoglycan and juxtaposed to the external side of the cytoplasmic membrane.

Turgor Is the osmotic pressure exerted by the cell contents against the cytoplasmic membrane as a consequence of the high intracellular concentration of metabolites and macromolecules.

Definition Statement

The peptidoglycan sacculus is a key structural component of the bacterial cell. Peptidoglycan metabolism is a complex process taking place in different cellular compartments. Present-day knowledge on the characteristics and central metabolic pathways of peptidoglycan metabolism is presented. The dynamic character of cell wall biology is given particular consideration.

Peptidoglycan is a fundamental component of the cell envelope of nearly all bacteria. It is a polymeric macromolecule made up of linear glycan chains cross-linked to each other by short peptide bridges. Peptidoglycan (or murein) is laid down on the outside of the cytoplasmic membrane as a covalently closed, netlike, macromolecular structure known as the cell wall or sacculus (small bag) (Figure 1). Preservation of cell integrity and determination of bacterial shape are the primary functions of the peptidoglycan. The netlike, covalently closed structure of the sacculus is particularly appropriate to maintain cell shape while standing the high (2 to more than 15 bar) turgor pressure exerted by the cytosol against the cytoplasmic membrane of the cell. Because the sacculus completely wraps the cell body, the cytoplasmic material has to adopt the shape of the relatively rigid sacculus (Figure 2). Therefore, variations in cell shape and size are constrained by a concurrent change of the sacculus itself. These characteristics together with the ability of isolated sacculi to accurately keep the shape of the original cell make the sacculus the bacterial equivalent to an exoskeleton (Figure 2). While bulk incorporation of new material is clearly necessary to enlarge the sacculus, the spatial distribution and temporal regulation of insertion events define the final shape of the bacterium.

The sacculus serves further important roles as a scaffold to support the external layers of the cell envelope (S-layers and the outer membrane (OM) of Gram-negative bacteria), in the biogenesis of supramolecular structures (export complexes and flagella), and in protein export in Gram-positive bacteria. Moreover, peptidoglycan is critically involved in developmental processes as the generation of resistance forms (spores) and appendages of different functions (prostheca).

Because peptidoglycan is exclusively found in bacteria and its biosynthetic pathway is both essential and highly conserved, it makes the ideal target for antibacterial drugs. Most of the commonly used antibiotics (β -lactams, glycopeptides, and fosfomycin) target enzymes involved in peptidoglycan biosynthesis.

A murein sacculus is present in all known bacteria with the remarkable exceptions of Mollicutes and the scrub typhus causative agent *Orientia tsutsugamushi*. Planctomycetes and Chlamydiae were also considered to lack a peptidoglycan sacculus until 2015 and 2013, respectively, when the application of new high-sensitivity methods demonstrated the presence of peptidoglycan in these organisms. The presence of some form of peptidoglycan in Chlamydiae was suspected because of the presence of most of the biosynthetic genes and because of their sensitivity to β -lactam antibiotics (the chlamydial anomaly). However, the biosynthetic route shows remarkable differences with other bacteria, in particular in the pathways for the synthesis of D-amino acids. The case of *O. tsutsugamushi* is also remarkable. This organism, formerly known as *Rickettsia tsutsugamushi*, has been separated from the genus *Rickettsia* mostly for the absence of a peptidoglycan sacculus, present in all other *Rickettsia*. Conversely, peptidoglycan layers entirely similar to bacterial sacculi are an essential structure in the photosynthetic organelles (cyanelles) of glaucophyte algae as *Cyanophora paradoxa*. This as well

[☆]Change History: May 2015. MA de Pedro updated Introduction, section text, Figures, and Further Readings.

This article is an update of M.A. de Pedro, Peptidoglycan (Murein), *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 453–469.

Figure 1 Basic structure and organization of the bacterial peptidoglycan sacculus.

as the recent identification of peptidoglycan biosynthesis genes in green plants (five genes in *Arabidopsis thaliana*) and mosses (nine genes in *Physcomitrella patens*) constitutes strong evidence supporting the endosymbiotic origin of eukaryotic organelles.

The exclusivity of peptidoglycan as a bacterial cell surface component has been successfully exploited by higher eukaryotes (plants and animals) as a means to recognize, and fight, bacterial infections. Indeed, peptidoglycan fragments (muropeptides) are recognized by specific 'peptidoglycan recognition proteins' (PGRPs), which are essential components of the innate immunity system in higher eukaryotes (with the exceptions of nematodes and plants) and play critical roles in antibacterial defense.

Because of peptidoglycan extracellular location and covalently closed nature, its biosynthesis represents a specially challenging problem to the bacterial cell. Precursors are synthesized in the cytoplasm but polymerization and attachment to the preexisting sacculus take place in the external environment, where there is no readily available source of metabolic energy. Besides, insertion of new precursors is not enough by itself to promote enlargement of the preexisting structure. Concomitant cleavage of chemical bonds in the sacculus is a strict requirement for growth. Therefore, both biosynthetic and degrading enzymes must work in concert for the sacculus to grow harmonically. In addition to the main biosynthetic pathway, rather complex by itself, peptidoglycan metabolism is further complicated by the nested intervention of pathways responsible for maturation, adaptive modifications, and recycling, not to mention species-specific pathways for the generation of resistance forms and/or specific appendages.

I will focus here on the more universal aspects of peptidoglycan composition, biosynthesis, and physical properties. Metabolism of the sacculus is intrinsically coupled with virtually all aspects of bacterial cell growth, division, development, and morphogenesis. However, treatment of such aspects in any detail would require a much more extensive and intensive treatment, out of the scope of this presentation.

Peptidoglycan Chemical Composition

Peptidoglycan composition and biosynthesis are fairly well established for a few model systems, but the base of knowledge is still relatively small. Not more than about 150 species have been studied to any detail and unexpected findings may indeed happen.

Figure 2 Peptidoglycan sacculi purified from shape mutants of *Escherichia coli*. Sacculi and whole cells of wild-type and mutant strains affected in cell morphology are compared to show how purified sacculi retain shape of the original cell. (a) Wild-type *E. coli* with normal rodlike shape, (b) spherical shape mutant affected in the *rodA* gene, (c) filament-shaped cells of a division thermosensitive *fts* mutant, (d) branched shaped cells from a *dacA* mutant grown in the presence of the cell division inhibitor aztreonam. Left panels are phase-contrast images of intact cells; right hand panels are TEM images of sacculi isolated from the corresponding strain. Images have been manipulated to approximate magnification of the phase-contrast and TEM images. The bars represent 1 μm . Notice the thinness of sacculi.

Traditionally, bacteria are divided into two main groups according to their response to the Gram stain: Gram-positive and Gram-negative. The distinction was established well before the discovery of peptidoglycan but reflects the basic dichotomy in the organization of the bacterial cell envelope. Gram-negative bacteria are characterized in structural terms by the presence of a thin peptidoglycan layer, surrounded by an asymmetrical OM made of an outer lipopolysaccharide leaflet and an inner phospholipid leaflet. The OM constitutes a permeability barrier to molecules of more than a few hundred dalton (a typical cutoff value is around 600 Da). As a result, the peptidoglycan layer is confined in a particular compartment defined by the OM and the cytoplasmic membrane, the periplasmic space (Figure 1). Conversely, Gram-positive bacteria display thick peptidoglycan layers, are devoid of OM, and have accessory polymers linked to the cell wall peptidoglycan (Figure 1). Gram-positive bacteria show a remarkable degree of chemical and structural variability in their cell walls, in contrast with the relatively homogenous nature of Gram-negative bacteria on these respects.

Peptidoglycan Basic Structure

The basic structural features of peptidoglycan are polymeric glycan strands cross-linked by short peptides. The canonical monomeric unit consists of the disaccharide N-acetylglucosamine (GlcNAc) (β -1 $\rightarrow$ 4) and N-acetylmuramic acid (MurNAc) substituted at the D-lactoyl group of MurNAc by a peptide stem with the sequence L-Ala-(γ)-D-Glu-*meso*A₂pm-D-Ala-D-Ala, known in short as the disaccharide pentapeptide. Successive monomers are linked to each other by (β -1 $\rightarrow$ 4) glycosidic bonds to form the glycan strands. Glycan strands become in turn cross-linked to each other through the stem peptides, normally between the amino acid at position four (invariably a D-Ala) in one strand and the dibasic amino acid at position three of the neighboring strand (Figure 1). Cross-linking can connect both amino acids either directly or through an intermediate short peptide (interpeptide bridge) that is added to the dibasic amino acid in the course of monomer unit biosynthesis. The monomeric subunits of peptidoglycan are commonly known as muropeptides.

The monomer is an unusual biomolecule characterized by the following features: (i) the presence of the rare MurNAc molecule, exclusively found in the bacterial sacculus and, oddly enough, in tissues of some gastropods; (ii) the presence of a (γ)-bonded D-Glu residue; (iii) the occurrence of L-D and D-D peptide bonds, never found in proteins; (iv) the existence of nonprotein amino acids (*meso*A₂pm, L-ornithine, and L-lanthionine); and (v) the presence of a C-terminal D-Ala-D-Ala dipeptide. These basic features are virtually universal. However, peptidoglycan from individual species normally presents modifications on this common theme, in both the glycan and the peptide moieties.

Structural Parameters of Peptidoglycan

The parameters more often used to describe the structural properties of peptidoglycan sacculi are cross-linkage and average glycan strand (chain) length.

Cross-linkage reflects the proportion of muropeptides that are covalently linked through peptide bonds bridging the respective stem peptides. Cross-linkage is normally expressed as the molar fraction of cross-linked with respect to total muropeptides in percentage. The higher the cross-linkage, the stronger, and stiffer, the peptidoglycan. Reported values show a large variability from species to species and also in response to environmental conditions (see section 'Postinsertional Metabolism of Peptidoglycan' in the succeeding text). Among Gram-positive bacteria, cross-linkage is habitually high, and values close to the theoretical 100% maximum have been reported (93% in *Staphylococcus aureus*). However, values for Gram-negative bacteria are much lower, ranging from 20% to 40% in most cases. This large difference is a consequence of the mostly monolayered arrangement of sacculi from Gram-negative bacteria. Geometric constraints limit the maximum theoretical cross-linkage to about 50% for a monolayer.

The length of the glycan strands is also a key structural parameter to understand the properties of the sacculus. Experimental determination of this parameter has been possible only in a very small number of cases. A major limitation comes from the fact that the length of glycan strands is not uniform but rather follows a very wide distribution. Precise data on the distribution of glycan strand lengths have only been obtained for *Escherichia coli*. In this organism, the average length is about 30 monomers, with a modal value of only 10 monomers. The distribution is very wide and strongly skewed towards the shorter length classes; nevertheless, about 30% of total muropeptides are in relatively long strands of more than 30 monomer units. In other bacteria, only an average value could be determined at best. The few data available indicate that peptidoglycan is predominantly made up of short glycan strands, with average lengths from 20 to 50 monomer units (*Helicobacter pylori*, *Bacillus subtilis*, *Bacillus licheniformis*, and *Streptococcus faecium*). However, as found for *E. coli*, glycan strands considerably longer than average might contribute substantially to the sacculus structure. Anyhow, it is important to realize that because a monomer unit is about 1 nm in length, and most bacteria are about or over 1 μ m in circumference, single glycan chains are by far too short to loop around the cell; therefore, a number of glycan strands have to be arranged 'head to tail' to encircle the cell.

Variations in the Glycan Moiety

The glycan backbone, which should consist exclusively of poly(GlcNAc-MurNAc), becomes invariably modified. Modification of the glycan moiety occurs in general at the late stages of synthesis, either associated to polymerization of the glycan strands or after insertion of new strands into the sacculus. The glycan strands of Gram-negative species have a residue of (1 $\rightarrow$ 6)-anhydro MurNAc as the 1-terminal saccharide, eliminating the reducing character that peptidoglycan should otherwise have. In Gram-positive

bacteria, covalent attachment of additional cell wall polymers, as teichoic acids, through phosphodiester bonds to GlcNAc or MurNAc is virtually universal.

Many species present secondary modifications in the glycan strands. O-acetylation, N-deacetylation, and N-glycolylation are the more common. These modifications often confer resistance against peptidoglycan-degrading enzymes, like the widespread muramidases (lysozyme), and modulate recognition of released muropeptides by the PGRPs of the host in pathogenic bacteria.

The most frequent modification of glycan chains is O-acetylation. This reaction, first detected in *Micrococcus luteus*, consists in the addition of an acetyl group to the C₆-OH of MurNAc residues, to form 2,6-N,O-diacetyl-MurNAc. O-acetylation occurs in both Gram-positive and Gram-negative species, including many important pathogens (*S. aureus*, *Streptococcus pneumoniae*, *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *H. pylori*, etc.). O-acetylation occurs at the level of polymerized peptidoglycan by means of O-acetyltransferases. Two types of O-acetyltransferases have been described: OatA-type O-acetyltransferases are single integral membrane proteins that simultaneously perform transport of acetate through the cytoplasmic membrane and transfer onto the MurNAc residues; Pat-type O-acetyltransferases are composed of two proteins, one for acetate transport and one for transfer to MurNAc. O-acetylation renders peptidoglycan resistant to most known muramidases and contributes to virulence of pathogens as staphylococci. Besides, O-acetylation prevents lysozyme clearing of cell wall fragments from blood serum after bacterial infection and contributes to induction of rheumatoid arthritis in humans.

Elimination of the N-acetyl groups at position 2 of either amino sugar increased peptidoglycan resistance to lysozyme in several important pathogens as *Bacillus anthracis*, *Listeria monocytogenes*, and *S. pneumoniae*. In all cases, known N-deacetylation takes place on polymerized peptidoglycan and known deacetylases are, or are predicted to be, extracytoplasmic enzymes. Interestingly, some of the redundant N-deacetylases present in *B. cereus* and *Bacillus anthracis* influence cell shape and cell separation, but have no effect on lysozyme resistance.

The presence of glycolyl residues instead of acetate at the 2 amino group of MurNAc was first found in *Mycobacterium smegmatis*. Later, it was clearly stated that N-glycolylation was a hallmark of the Actinomycetales. Contrary to the modifications discussed earlier, N-glycolylation occurs at the stage of UDP-linked precursors in the biosynthesis of the monomeric subunit by the action of a monooxygenase in the presence of molecular oxygen and NADPH. As in the previous cases, impairment of the glycolylating enzyme results in hypersensitivity against lysozyme and β -lactam antibiotics.

Variations in the Sequence of the Stem Peptide

The stem peptide sequence shows a considerable degree of variability, but, in most cases, alterations can be viewed as conservative, in as much as the basic features are concerned. Variations in the stem peptide sequence are dictated either by the specificity of the biosynthetic enzymes or by postsynthetic modification of the otherwise standard sequence.

Replacement of the canonical amino acid (L-Ala) at position one is rare and only a few cases are known where Gly (*Mycobacterium leprae* and *Brevibacterium imperiale*) or L-Ser (*Butyrivibacterium rettgeri*) substitutes for the regular L-Ala.

In all species studied so far, the amino acid at position two is invariably D-Glu.

The third amino acid in the stem, usually a dibasic amino acid, shows the higher variability. Most often, A₂pm (most Gram-negative bacteria but also bacilli and mycobacteria) or L-Lys (most Gram-positive species) occupies the third position. However, in a number of species, this position is occupied by unusual dibasic amino acids as L,L-diaminopimelic acid (*Streptomyces albus*), L-ornithine (*Spirochetes*, *Thermus thermophilus*, and *Deinococcus radiodurans*), meso-lanthionine (*Fusobacterium*), or L-2,4-diaminobutyrate (*Corynebacterium aquaticum*). In a few instances, monoamino acids also take the third position as in *Corynebacterium poinsettia* (L-homoserine) and *Erysipelothrix rhusiopathiae* (L-Ala). Another interesting exception is the case of a few species where the third position is occupied by two amino acids as in *Bifidobacterium globosum* in which either L-Lys or D-Lys can be at position three because of poor substrate specificity of the adding enzyme.

Amino acids at positions 4 and 5 consist almost invariably of D-Ala. The D-Ala-D-Ala terminal dipeptide is perhaps the most widely known peptidoglycan hallmark. However, a certain proportion of Gly is often found at these positions because of the lack of selectivity of D-Ala-D-Ala ligase, the enzyme making the dipeptide. The proportion of Gly is normally quite low ($\leq 1\%$) but in some species as *Caulobacter crescentus* can be as high as 19%. Undoubtedly, the most relevant alteration known has been recently identified in some strains of enterococci. In such strains, D-lactate or D-Ser substitutes for the D-Ala at position five. The modification is associated with development of high-level resistance against the antibiotic vancomycin. Vancomycin binds D-Ala-D-Ala with high affinity and blocks the late steps of peptidoglycan biosynthesis. However, the depsipeptide D-Ala-D-Lac is a very poor substrate for vancomycin, and therefore, substitution of D-Lac for D-Ala prevents antibiotic action. Actually, this mechanism of resistance is a serious clinical problem.

Secondary Modifications of the Stem Peptide

Other variations in the chemical composition of monomer peptide stem (amidation, acetylation, attachment of additional amino acids, etc.) occur at later stages by the modification of the otherwise regular monomeric subunit. These modifications more often affect amino acids at positions 2 and 3. Amidation of D-Glu and meso-A₂pm at the α and ϵ carboxyl groups, respectively, is quite common in Gram-positive bacteria. The membrane-bound form of the complete monomer is the substrate for amidation. Hydroxylation of D-Glu, meso-A₂pm, and L-Lys has been found in some species in direct relation with oxygenation levels. Addition of aminated compounds to the α -carboxyl group of D-Glu at position 2 has been documented in some organisms, as *M. luteus* (Gly)

and *Arthrobacter* (glycine amide) and also in peptidoglycan from *C. paradoxa* cyanelles (N-acetylputrescine). In many Gram-positive species, the third amino acid is often modified at the level of lipid I by addition of a short (1–7 amino acids), highly variable, peptide to the free amino group, which acts as an intermediate bridge in cross-linking reactions between peptide stems.

The peptide stem constitutes in addition the anchoring point for specific cell envelope proteins. Gram-negative enterobacteria often present a small-size lipoprotein (the 58-amino acid Braun's lipoprotein in *E. coli*) as the only known molecule covalently bound to murein. Murein-bound lipoprotein anchors the OM to the sacculus. The acylated N-terminal domain of the lipoprotein is buried into the phospholipid inner leaflet of the OM, while the ϵ -amino group of the C-terminal L-Lys becomes attached to the α -carboxyl group of *meso*-A₂pm, by means of a transpeptidation reaction, effectively bridging both cell envelope layers.

Gram-positive bacteria in general present a larger number of peptidoglycan-bound proteins, often involved in pathogenic processes. Binding is mediated by cytoplasmic membrane proteins denominated sortases. Sortases, exemplified by sortase A from *S. aureus*, recognize specific C-terminal sorting sequences in the exported proteins. The recognition event triggers a transpeptidation reaction between a peptide bond in the sorting sequence and the free amino group of a translocated molecule of lipid II (see section 'Synthesis of Lipid Intermediates'). Then, the protein-bound lipid II molecules enter the peptidoglycan polymerization pathway, pulling the proteins outward as the cell wall grows.

Biosynthesis of Peptidoglycan Monomer Units

Biosynthesis of peptidoglycan has been the matter of active research for more than 60 years. From these efforts, an overall view of the process thought to be valid for all bacteria has emerged.

Peptidoglycan biosynthesis is traditionally divided in two stages on the basis of the cell compartments where it takes place. The first stage concerns assembly of the monomer unit in the intracellular space by enzymes sitting in the cytoplasm or in the cytoplasmic membrane inner leaflet. The end product of the first stage is a membrane-anchored, lipid intermediate: disaccharide-pentapeptide pyrophosphate undecaprenol (lipid II) (Figure 3). The second stage addresses the extracellular polymerization steps that take place at the outer side of the cytoplasmic membrane and use the lipid intermediate as the initial substrate (Figure 4). Concomitantly with polymerization, nascent peptidoglycan is inserted into the macromolecular structure of the sacculus, in a way promoting further physical expansion of the preexisting structure and ensuring preservation of proper shape.

Assembly of the monomer can be subdivided into four stages: synthesis of UDP-GlcNAc, synthesis of UDP-MurNAc, sequential formation of UDP-MurNAc-peptides, and synthesis of the lipid-linked intermediates (Figure 3).

Synthesis of UDP-GlcNAc

Synthesis of UDP-GlcNAc occurs in four reactions. The first reaction is the conversion by the GlmS protein (glucosamine-6-phosphate synthase) of fructose 6-phosphate and glutamine into glucosamine-6-phosphate, which is isomerized to glucosamine-1-phosphate by GlmM protein (phosphoglucosamine mutase). Activity of GlmM is regulated by phosphorylation of a serine at the active site and seems to be the checkpoint in the regulation of UDP-GlcNAc synthesis. The final two steps are catalyzed sequentially by the bifunctional enzyme GlmU. The C-terminal domain of GlmU has glucosamine-1-phosphate acetyltransferase activity and catalyzes transfer of an acetyl group from acetyl CoA to the amino group of glucosamine-1-phosphate, while the N-terminal domain, endowed with N-acetylglucosamine-1-phosphate uridylyltransferase activity, uridylylates the product of the previous reaction in the presence of UTP, producing UDP-GlcNAc. The intracellular concentration of UDP-GlcNAc is the limiting factor for the subsequent steps in peptidoglycan biosynthesis.

Synthesis of UDP-MurNAc

UDP-MurNAc is synthesized from UDP-GlcNAc in a two-step process involving, first, transfer of enolpyruvate from phosphoenolpyruvate to the C₃-OH of a UDP-GlcNAc molecule by the MurA transferase (UDP-N-acetylglucosamine enolpyruvyl transferase) to yield UDP-GlcNAc-enolpyruvate and, second, reduction of enolpyruvate to D-lactate by the MurB reductase (UDP-N-acetyl-enolpyruvylglucosamine reductase) in the presence of NADPH to make UDP-MurNAc.

Addition of the Stem Peptide

Addition of the stem peptide is a sequential process in which L-Ala; D-Glu; a dibasic amino acid, most often *meso* A₂pm or L-Lys; and the dipeptide D-Ala-D-Ala are incorporated into UDP-MurNAc to produce UDP-MurNAc-pentapeptide. Amino acids are added stepwise by the highly specific synthases MurC (UDP-N-acetylmuramic acid:L-alanine ligase), MurD (UDP-N-Acetylmuramyl-L-alanine:D-glutamate ligase), MurE (UDP-N-Acetylmuramyl-L-alanyl-D-glutamate:*meso*-diaminopimelate ligase), MurF (UDP-N-acetylmuramyl-L-alanyl-D-glutamyl-*meso*-diaminopimelate:D-alanyl-D-alanine ligase), and D-alanine:D-alanine ligase, which synthesizes the dipeptide D-Ala-D-Ala, the substrate for MurF. All these ligases are ATP-dependent and have a similar catalytic mechanism: activation of the C-terminal amino acid of the growing nucleotide precursor to an acyl phosphate intermediate at the expense of ATP, followed by a nucleophilic attack by the NH₂ group of the added amino acid leading to release of phosphate and formation

Figure 3 Schematic representation of peptidoglycan monomer unit biosynthesis. The individual stages, synthesis of N-acetylglucosamine, synthesis of N-acetylmuramic acid, addition of the stem peptide, and synthesis of lipid-linked precursors, are differentiated by colors. Cosubstrates required for each step are highlighted in red. Enzymes are indicated by their short names derived from the genetic *E. coli* nomenclature that corresponds to GlmS, glucosamine-6-phosphate synthase; GlmM, phosphoglucosamine mutase; GlmU, glucosamine-1-phosphate acetyltransferase plus N-acetylglucosamine-1-phosphate uridylyltransferase; MurA, UDP-N-acetylglucosamine enolpyruvyl transferase; MurB, UDP-N-acetylenolpyruvylglucosamine reductase; MurC, UDP-N-acetylmuramic acid:L-alanine ligase; MurD, UDP-N-acetylmuramoyl-L-alanine:D-glutamate ligase; MurE, UDP-N-acetylmuramoyl-L-alanyl-D-glutamate:meso-diaminopimelate ligase; MurF, UDP-N-acetylmuramoyl-L-alanyl-D-glutamyl-meso-diaminopimelate:D-alanyl-D-alanine ligase; MurG, UDP-N-acetylglucosamine:N-acetylmuramyl(pentapeptide)-P-undecaprenol-N-acetylglucosamine transferase; and MurA, phospho-N-acetylmuramyl-pentapeptide translocase.

Figure 4 Schematic representation of peptidoglycan polymerization. In the first step, lipid II precursor molecules are transferred to the external side of the cytoplasmic membrane by the flippase MurJ. Once on the outside, a lipid II molecule interacts with the transglycosylase domain of a bifunctional class A high-molecular-weight PBP. A nascent glycan strand, already attached to the sacculus at the distal end, is transferred from undecaprenyl phosphate onto the C₄-OH of the lipid II molecule in the transglycosylase domain, causing the glycan strand to grow by one unit. A molecule of undecaprenyl pyrophosphate is also released and, upon transfer to the cytoplasmic side of the membrane, undergoes a new round of synthesis. Concomitantly, a stem peptide from the nascent chain and the second stem peptide in the preexisting sacculus find the right relative positioning at the transpeptidase domain active site and become cross-linked by the transfer of the peptide bond between the two terminal D-Ala residues of the stem peptide in the nascent glycan strand to the dibasic amino acid in the stem peptide at the sacculus, releasing a molecule of D-Ala. Iteration of the process leads to coordinated glycan strand linear polymerization and insertion of the nascent strands into the netlike structure of the sacculus.

of a new peptide bond. The specificity of both MurE and MurF is variable according to the dibasic amino acid present at position 3 of the stem peptide, a species-specific feature.

Synthesis of Lipid Intermediates

Attachment of the soluble precursors to the isoprenoid lipid undecaprenyl phosphate (bactoprenol) in the cytoplasmic membrane marks the beginning of the membrane-bound phase of peptidoglycan biosynthesis. The first reaction consists in the transfer of phospho-MurNAc-pentapeptide from UDP-MurNAc-pentapeptide to the membrane acceptor undecaprenyl phosphate to yield MurNAc-(pentapeptide)-pyrophosphoryl-undecaprenol (lipid I) and UMP. The reaction is catalyzed by the MurA translocase (phospho-N-acetylmuramyl-pentapeptide translocase), an integral membrane protein. In a consecutive reaction, the MurG transferase (UDP-N-acetylglucosamine:N-acetylmuramyl(pentapeptide)-P-P-undecaprenol-N-acetylglucosamine transferase) catalyzes the addition of a residue of GlcNAc from UDP-GlcNAc to the MurNAc moiety of a lipid I molecule through a (β -1 $\rightarrow$ 4) glycosidic bond giving the completed lipid-linked monomer unit UDP-GlcNAc-(β -1 $\rightarrow$ 4)-MurNAc(pentapeptide)-pyrophosphoryl-undecaprenol (lipid II). In *E. coli*, MurG is a peripheral membrane protein associated to the inner leaflet of the cytoplasmic membrane.

In growing cells, the proportion lipid I to UDP-MurNAc-pentapeptide is very low, in the 1% range, indicating that availability of undecaprenyl phosphate is a limiting factor for the membrane-bound steps of peptidoglycan biosynthesis. The scarcity of lipid I and lipid II (c.700 and 2000 molecules per cell in *E. coli*) implies a high turnover rate (about 1 s). This, in turn, constrains free diffusion of lipid precursors as an efficient way to sustain ongoing synthesis and supports the existence of associations with the transferases and later acting proteins in peptidoglycan-synthesizing complexes. Indeed, recent evidence gathered from *E. coli* supports an association of MurG with the synthetic complexes responsible for longitudinal growth of the sacculus.

Addition of Interpeptide Bridges

In many Gram-positive bacteria, cross-linking between peptidoglycan stem peptides occurs with the concurrence of a short peptide, which is added to the dibasic amino acid at position 3. The size and composition of the interpeptide bridges are species-specific features. Size ranges from one to seven amino acids and composition includes Gly as well as D-amino acids (D-Ser, D-Glu, and D-Asx) and L-amino acids (L-Ala and L-Glu). The nature of the interpeptide bridges is the main cause of variability in peptidoglycan. However, knowledge of the enzymes involved (branching enzymes) is still limited. Synthesis of the interpeptide bridge occurs by

the sequential addition of amino acids to a pentapeptide precursor. The precursor substrate for branching enzymes is variable among species; for instance, in *S. aureus*, it is lipid II, but in other species, it can be lipid I and also UDP-MurNAc-pentapeptide. Furthermore, in some instances, the branching enzymes use more than one substrate (lipid II and UDP-MurNAc-pentapeptide in *Enterococcus faecalis*). Two different mechanisms coexist in dependence of the nature of the amino acid to be added. L-amino acids and Gly are activated as amino acyl-tRNAs and added to the precursor by the nonribosomal peptide-forming enzymes Fem transferases. D-amino acids are incorporated by enzymes of the ATP-grasp family. These enzymes activate the amino acids as acyl phosphates at the expense of ATP and catalyze ligation of the activated carboxyl to different chemical groups, in particular amino and imino nitrogens.

Polymerization of Peptidoglycan

The second stage in peptidoglycan synthesis is polymerization of monomer units and incorporation of the new polymeric product into the preexisting sacculus in such a fashion as to promote growth and preserve the correct cell shape.

The polymerization stages are performed by two different membrane-bound activities: glycosyltransferases that catalyze the formation of linear glycan polymers and peptidyl transferases (transpeptidases) that catalyze cross-linking of stem peptides. In growing bacteria, formation of glycan strands (transglycosylation) and cross-linking of stem peptides (transpeptidation) are continuous, tightly coupled reactions. However, detailed analysis of the process indicates that polymerization of the monomer proceeds by transglycosylation and precedes cross-linking of the nascent glycan strands by transpeptidation. It is important to realize that transpeptidation is responsible not only for the cross-linking of nascent material but also for its incorporation into the sacculus (Figure 4).

Translocation of Lipid-Linked Precursors

Polymerization of peptidoglycan is an extracellular process, but the immediate precursor lipid II is synthesized in the intracellular side of the cytoplasmic membrane. Therefore, the lipid II units must be translocated to the external side of the membrane (Figure 4). Lipid II translocation has been a long-standing controversial point, only recently settled by the demonstration of the protein MurJ, formerly known as MviN, as the lipid II flippase in *E. coli*. The experiments leading to the identification of MurJ as the flippase discard previous hypotheses in favor of the morphogenetic proteins RodA and/or FtsW. MurJ is a cytoplasmic membrane protein belonging to the multidrug/oligosaccharidyl-lipid/polysaccharide exporter superfamily of proteins. It has 14 transmembrane domains and a solvent-exposed cavity within its transmembrane region, which is essential for the flippase activity. As expected from its function, the MurJ protein is essential and its impairment leads to cell death. Whether MurJ-like mechanisms are unique and universal is still unknown, and other alternatives might be found.

Penicillin Binding Proteins: The Key Peptidoglycan Synthases

Penicillin binding proteins (PBPs) are a set of minor cytoplasmic membrane proteins ubiquitous in bacteria. PBPs are the specific targets for β -lactam antibiotics and critically involved in the late stages of peptidoglycan synthesis. PBPs are defined by their ability to covalently bind β -lactams yielding stable, enzymatically inactive, acyl-enzyme complexes. This property facilitated identification of PBPs by specific labeling with radioactive or fluorescent β -lactams. PBPs apparently share a common topology; they are anchored to the cytoplasmic membrane through a transmembrane domain, but the bulk of the protein is exposed to the external environment in close apposition to the sacculus, the PBP's insoluble substrate. Virtually every known bacterium possesses a set of PBPs, but number, size, abundance, and β -lactam binding spectrum are variable from species to species.

PBPs are habitually classified as high (>45 kDa)- and low (<45 kDa)-molecular-weight PBPs (HMW- and LMW-PBPs, respectively). The difference in molecular weight does indeed reflect a functional dichotomy: while HMW-PBPs have polymerase activity, LMW-PBPs are more often involved in cleavage of peptidoglycan peptide bonds and display endopeptidase and carboxypeptidase activities. The number of reactions that a single polypeptide is able to catalyze differentiates two classes of HMW-PBPs: the class A HMW-PBPs, which are bifunctional enzymes able to catalyze both polymerization of the glycan strands (transglycosylation) and cross-linking of the stem peptides (transpeptidation), and class B HMW-PBPs, which are monofunctional enzymes endowed with transpeptidase activity only.

Genetic analysis of HMW-PBPs in known bacterial genomes embodying more than 400 class A and 300 class B HMW-PBPs demonstrated a clear modular architecture. Both classes present a short cytoplasmic N-terminal segment, followed by a single transmembrane domain followed in class A enzymes by the transglycosylase module and in class B by a shorter module of unknown function, followed in turn by the C-terminal transpeptidase (peptidyl transferase) module responsible for cross-linking and β -lactam binding. The intermediate module in class B enzymes has been proposed to be involved in interactions with other membrane proteins. LMW-PBPs are monofunctional peptidyl transferases most often endowed with D,D-carboxypeptidase activity and with D,D-endopeptidase activity. As mentioned earlier, the active site of the peptidyl transferase is the target for β -lactam binding. Proteins of this group have an unusual architecture; the peptidyl transferase domain is encoded after a cleavable peptide signal, and the protein is anchored to the membrane through a C-terminal transmembrane domain or amphipathic helix.

Synthesis of Linear Peptidoglycan Polymers

Polymerization of peptidoglycan lipid II units is catalyzed by the bifunctional transglycosylase–transpeptidase class A HMW-PBPs. Many class A HMW-PBPs are known, but most of present-day knowledge derives from *E. coli* PBP1B, the paradigmatic peptidoglycan synthase.

The full-length enzymatically active PBP1B seems to be a dimer. The most widely accepted mechanism for peptidoglycan polymerization involves the repetitive addition of disaccharide-pentapeptide units from lipid II at the reducing end of a growing glycan chain attached to a second molecule of undecaprenyl pyrophosphate. In such a scheme, the undecaprenyl pyrophosphate-bound growing glycan chain acts as the glycosyl donor and is transferred to the C₄-OH of the GlcNAc molecule in a lipid II molecule, which becomes the glycosyl acceptor substrate. While the nascent glycan strand grows by a monomer unit each cycle, the reaction generates free undecaprenol pyrophosphate, which is transferred back to the cytoplasmic side of the membrane, hydrolyzed to undecaprenol phosphate, and reused for a new addition cycle (Figure 4).

The exact catalytic mechanism for transglycosylation is still uncertain. It is likely that the transglycosylase domain of the PBP recognizes the sugar moieties of both the lipid II and a terminal section of the growing glycan chain, as is characteristic for other related glycosyl transferases. It has been proposed that the γ -COOH of an active site Glu residue (Glu₂₂₃ in *E. coli* PBP1B) donates its proton to the phosphoester bond of the growing chain, to give an oxocarbenium cation, which then undergoes nucleophilic attack by the 4-OH of the GlcNAc in the lipid II molecule. Additional Asp and Glu residues in the active site (Asp₂₃₄ and Glu₂₉₀ in *E. coli* PBP1B) are likely involved in the stabilization of the oxocarbenium and activation of the C₄-OH group.

As mature peptidoglycan is devoid of any linkage to undecaprenyl phosphate, some enzymatic reaction must release nascent polymers from the membrane-anchoring undecaprenyl-phosphate moiety. Such enzyme(s) could play an important role in determining the length of the resulting peptidoglycan strands. However, there is no knowledge for any such enzyme so far. Release of the nascent glycan strand from undecaprenol pyrophosphate in Gram-negative bacteria results in generation of (1 → 6)-anhydro MurNAc, which becomes a tag for the glycan chain terminal mucopeptide. Formation of (1 → 6)-anhydro MurNAc is thought to occur because transglycosylases may enter an idling state that results in an intramolecular glycosyl transfer of the nascent glycan strand onto the C₆-OH of the MurNAc residue, instead of the C₄-OH of a nearby lipid II molecule. A possible alternative is that glycan strands are polymerized in a continuous fashion and then are trimmed by the so-called lytic-transglycosylase enzymes able to split glycan polymers generating (1 → 6)-anhydro MurNAc (see section ‘[Brake to Make: Peptidoglycan Hydrolases](#)’). The presence of (1 → 6)-anhydro MurNAc in the glycan strand terminal mucopeptides is the reason for the nonreducing character of peptidoglycan in Gram-negative bacteria.

Class A HMW-PBPs clearly take the burden of lipid II polymerization. Nevertheless, membrane-bound monofunctional glycosyl transferases (MGTs), able to polymerize Lipid II, have been identified and biochemically characterized in a number of unrelated bacteria as *M. luteus*, *E. coli*, *B. subtilis*, *Brucella abortus*, *Enterococcus faecalis*, *Haemophilus influenza*, *S. pneumonia*, and *S. aureus*. MGTs share considerable similarity with the glycosyl transferase domains of class A PBPs. In those species where it has been studied, MGTs often account for most of the lipid II glycosyl transferase activity in *in vitro* assays with cell extracts. MGTs are dispensable proteins, suggesting an auxiliary function. However, in the particular case of *S. aureus*, MGT exhibits a synthetic lethal phenotype with mutations in the transglycosylase domain of PBP2, indicative of a certain degree of functional overlapping.

An intriguing aspect of peptidoglycan synthetic transglycosylases, indeed of most enzymes acting on macromolecular peptidoglycan, is their high redundancy. For instance, both *E. coli* and *S. pneumoniae* have at least four different enzymes each. It is believed that this multiplicity reflects a variety of functions. In fact, not all transglycosylases are essential. As an example, in *E. coli*, both the class A PBP1C and Mgl can be deleted without noticeable harm to the cell. However, either PBP1A or PBP1B must be present. It has been proposed that nonessential transglycosylases could be involved in localized reorganizations of the cell sacculus required for the assembly of envelope spanning complexes, such as flagella, and for specialized transport processes through the envelope.

Cross-Linking of Glycan Chains

In the last step, peptidoglycan strands synthesized by glycosyl transferases must be incorporated into the macromolecular, netlike structure of the sacculus. This is the role of the peptidyl transferase activities (D,D-transpeptidase) displayed by both class A and class B HMW-PBPs.

Transpeptidases cross-link stem peptides in the sacculus to the stem peptides in the nascent glycan strands, which, consequently, become part of the sacculus proper (Figure 4). The canonical D,D-transpeptidation reaction consists in the transfer of the D,D peptide bond linking the C-terminal D-Ala-D-Ala dipeptide of a disaccharide-pentapeptide unit in one strand, the donor mucopeptide, onto the free NH₂ group of the dibasic amino acid at position 3 in the stem peptide of a second (acceptor) mucopeptide in a nearby strand (Figure 4).

The transpeptidation reaction, the target for β -lactam antibiotics, has been analyzed in detail. The reaction proceeds in two steps. First, the transpeptidase domain binds the stem peptide -D-Ala-D-Ala dipeptide, and through a nucleophilic attack to the amide bond by the -OH of an active site Ser residue, an acyl–enzyme complex is formed. In a second step, the newly formed ester bond between the D-Ala at position 4 of the donor and the active site Ser is subjected to nucleophilic attack by the free NH₂– group of the dibasic amino acid in the acceptor stem peptide, resulting in the formation of a new amide bond bridging both stem peptides and regeneration of the -OH in the active site Ser. As a result of the transpeptidation reaction, the free NH₂ of the dibasic amino acid in the acceptor moiety of the resulting cross-linked peptide becomes substituted and unable to participate in further transpeptidation

reactions. Conversely, the equivalent group in the donor moiety remains free and capable to act as acceptor in a subsequent round of transpeptidation to yield higher-order cross-linked muropeptides. Indeed, tetramers have been demonstrated in *E. coli* and in a number of both Gram-negative and Gram-positive bacteria (*S. pneumoniae*) where they are particularly abundant.

As indicated before, in most Gram-positive bacteria, the stem peptide is modified by acylation with a short peptide of the non- α -NH₂ group of the dibasic amino acid. In these cases, the transpeptidation reaction proceeds as mentioned earlier except that the nucleophile in the second step of the reaction normally is the N-terminal NH₂ of the interpeptide bridge.

β -Lactam antibiotics react with D,D-transpeptidases, in general D,D-peptidyl transferases, because they mimic the natural donor substrate and are recognized by the donor site in the peptidyl transferase. The β -lactam bond substitutes for the D-Ala $\rightarrow$ D-Ala amide bond and acylates the active site serine residue yielding a stable penicilloyl-enzyme complex, which disables the enzyme.

With all likelihood, D,D-transpeptidation is the universal cross-linking reaction and the reason for the wide spectrum of β -lactam antibiotics. However, cross-linking by transfer of L,D peptide bonds has also been described in several bacteria. The dibasic amino acid at position 3 (A₂pm, L-Lys) can substitute for D-Ala at position 4 as the acyl donor in the transpeptidation reaction to yield a (3 $\rightarrow$ 3) L,D cross-link, instead of the regular (3 $\rightarrow$ 4) D,D cross-link produced by D,D-transpeptidases. In this case, the transferred peptide bond is of L,D conformation. The (3 $\rightarrow$ 3) L,D cross bridges were originally found in *Mycobacteria*. In some species as *M. smegmatis*, they account for as much as one-third of total cross bridges. In other bacteria, proportion is highly variable. In Gram-negative bacteria with (3 $\rightarrow$ 3) L,D cross bridges (often referred to as A₂pm $\rightarrow$ A₂pm cross bridges), the relative abundance is widely variable. In most cases, they account for below 15% of total cross bridges, but can represent up to 45% as in *Agrobacterium tumefaciens*. However, abundance of L,D cross bridges shows a substantial variability in response to environmental conditions, with a tendency to increase under stress conditions. At present, there is no clear understanding of the biochemistry of (3 $\rightarrow$ 3) L,D cross-links. It is generally accepted that synthesis occurs by a mechanism formally similar to D,D-transpeptidation, except for the nature of the donor peptide bond. Such a mechanism would be catalyzed by L,D-transpeptidases. In fact, L,D-transpeptidases have been described and characterized in some bacteria (*Enterococcus faecium*, *V. cholera*, and *E. coli*). L,D-transpeptidases are cysteine-peptidyl transferases unrelated to PBPs and consequently refractory to inhibition by most β -lactam antibiotics. Indeed, L,D-transpeptidases have been associated with β -lactam resistance. Computer modeling of L,D- and D,D-cross-linked muropeptides reveals substantial conformational differences, indicative of specific functionalities in the sacculus.

Class A versus Class B HMW-PBPs

As indicated before, both classes have D,D-transpeptidase activity, but only class A HMW-PBPs are bifunctional enzymes. Therefore, while class A HMW-PBPs are able to both polymerize lipid II into strands and incorporate the strands into the sacculus, class B HMW-PBPs are limited to the cross-linking of peptidoglycan strands necessarily fed to them by ancillary transglycosylases. However, in all bacteria where PBPs could be well studied, class B PBPs are essential and key enzymes for proper morphogenesis. For instance, PBP2 of *E. coli* is strictly required for longitudinal growth of the sacculus, and PBP3 is responsible for the synthesis of the septum when cells divide. Furthermore, it has been shown that PBP2 is by itself able to promote substantial growth of the sacculus under specific conditions. A possible interpretation of available information, by no means complete, is that class A enzymes provide bulk-synthetic capacity and class B enzymes direct the very final step of the process, fine-tuning incorporation of new material as to ensure proper shape is generated. Whether class A HMW-PBPs are feeders for class B or class B HMW-PBPs are associated with monofunctional glycosyl transferases is under discussion. However, the fact that at least in *E. coli*, MGT is dispensable but a class A enzyme must be active for the cells to grow favors class A and class B enzymes teaming together.

Brake to Make: Peptidoglycan Hydrolases

Enzymes capable of cleaving specific bonds in the sacculus are expected to play crucial roles to permit expansion of the whole structure. These enzymes are generally referred to as murein, or peptidoglycan, hydrolases. Some, but not all, cleave bonds that affect the physical continuity of peptidoglycan. Enzymes able to split cross-links or glycan strands can weaken the sacculus beyond a point when it is not more able to withstand the turgor pressure of the cell, and cell lysis would ensue. Therefore, murein hydrolases are dangerous enzymes for the cell, which must subject them to very stringent control. The capacity of some of them to cause cell lysis when control mechanisms are upset, by antibiotics, for instance, led to the designation of 'autolysins.' The number and variety of murein hydrolases are really staggering. Specific hydrolases exist for each and every peptide and glycosidic in peptidoglycan. Each bacterial species studied showed a wide repertory of hydrolases and very often a high degree of redundancy for at least some activities. To give a taste, in *E. coli*, not <5 different hydrolytic activities, represented by not <16 different proteins, have been described.

Peptidoglycan hydrolases can be roughly classified according to their substrate in peptidases and glycosylases. The former cleave bonds in the stem peptide and the later on the glycan strand.

An important group of peptidases comprises the D,D- and L,D-endopeptidases and carboxypeptidases, widespread and redundant in most bacteria. D,D-endopeptidase and D,D-carboxypeptidase activities are peptidyl transferases associated to low-molecular-weight PBPs. D,D-endopeptidases cut the cross bridges attaching nearby glycan strands to each other by cleaving the amide bond between the D-Ala at position 4 of the donor stem peptide and the dibasic amino acid on the acceptor stem peptide. Thus, a D,D-endopeptidase reverts the action of a D,D-transpeptidase. D,D-carboxypeptidases remove the C-terminal D-Ala from the stem peptides, which become shortened to tetrapeptides. Both sets of enzymes are generally dispensable but likely relevant for proper

morphogenesis. Impairment of their activity in *E. coli*, for instance, leads to severe morphological abnormalities as branching (Figure 2, panel D). The catalytic mechanism of these enzymes is similar to HMW-PBPs. In the case of D,D-transpeptidases, the donor amino acid is the D-Ala at position 4 in the donor side of the cross bridge, while for D,D-carboxypeptidases, it is the equivalent D-Ala in a non-cross-linked stem peptide. Upon the formation of the acyl-enzyme complex, the former acceptor moiety is released and the NH₂- group of the acceptor amino acid is regenerated. The ester bond between the donor peptide and the active site serine is then subjected to nucleophilic attack by a molecule of water releasing the free peptide and regenerating the active site amino acid. Because of their PBP character, most D,D-endopeptidases and carboxypeptidases are inhibited by β -lactams. However, in some bacteria as *E. coli*, penicillin-insensitive D,D-endopeptidases (MepA) have been also identified. The MepA-type endopeptidases are metallopeptidases completely unrelated to the penicillin-sensitive ones. L,D-endopeptidases and L,D-carboxypeptidases have similar activities to their D,D-counterparts on peptide bonds of L,D-stereochemistry and in most cases are believed to proceed through similar catalytic mechanisms.

A second very relevant set of murein peptidases is composed by the N-acetylmuramyl-L-alanine amidases. These enzymes cleave the amide bond between the lactyl group in MurNAc and the first amino acid (L-Ala) in the stem peptide. As a result of their activity, stem peptides are released from the peptidoglycan strands. Enzymes with this activity are quite heterogeneous in function and structure and still not fully characterized. Amidases are widespread and very often highly redundant. In *E. coli*, at least five molecular species present this activity. In some Gram-positive bacteria, amidases often present additional domains able to recognize, and bind to specific motifs in cell wall polymers, as the teichoic and lipoteichoic acids. Recognition of these domains might be required for enzyme activation as is the case for *S. pneumoniae* LytA, which has to recognize lipoteichoic acid choline to become active.

Among the glycosylases, the family of lytic transglycosylases is predominant. These enzymes catalyze the intramolecular transfer of a MurNAc (β -1 $\rightarrow$ 4) GlcNAc glycosidic bond in a peptidoglycan strand onto the 6-OH of the MurNAc residue, cleaving the glycan strands and generating (1 $\rightarrow$ 6)-anhydro MurNAc-containing mucopeptides. Both endo- and exolytic transglycosylases have been identified. Exolytic enzymes are processive enzymes that degrade peptidoglycan strands from one end (GlcNAc) releasing a monomer at a time and shortening the strand by one unit. Endolytic enzymes randomly cleave MurNAc (β -1 $\rightarrow$ 4) GlcNAc glycosidic bonds in the glycan strand cutting it into a number of pieces.

N-acetylmuramidases (as lysozymes) and N-acetyl-glucosaminidases are the more frequent glycosyl hydrolases. The later are often predominant in some Gram-positive species, as *S. aureus*, where they are definitely involved in the morphogenetic pathway. However, both classes of enzymes seem to be mostly implicated in degradative processes as autolysis, peptidoglycan turnover, and even depredation (many bacteria release enzymes able to degrade peptidoglycan of niche-sharing species), than on biosynthetic pathways.

Physiology of Peptidoglycan Hydrolases

For the bacterial cell to grow, the sacculus has to expand accordingly. Because the sacculus is a covalently closed structure, just binding (cross-linking) new peptidoglycan strands to the sacculus is not enough to promote expansion. Indeed, it would only lead to thickening of the wall. To enlarge a closed net bag, meshes have to be cleaved, to permit insertion of new material between the existing nettings. However, the multiplicity of murein hydrolases as well as the high redundancy of many of them made investigation of their functionality a particularly frustrating business. It took more than 30 years of systematic work to identify the hydrolases responsible for peptidoglycan expansion in the model bacteria *E. coli*. Three different D,D-endopeptidases, MepS, MepH, and MepM (formerly Spr, YdhO, and YebA), turned out to be redundantly essential for the growth of the sacculus. In the absence of the three proteins cell wall growth is inhibited, and cell death ensues. Unexpectedly, impairment of these proteins results in inhibition of the insertion of new precursors into the sacculus, indicating the existence of a regulatory event, which impedes the activity of the synthases under such conditions. Interestingly, the three endopeptidases have quite different characteristics. MepS and MepH are both cysteine peptidases, but while MepS is an OM lipoprotein, MepH seems to be a periplasmic protein. MepM is a Zn²⁺-dependent metallopeptidase anchored to the cytoplasmic membrane. The existence of different pathways to promote controlled opening of the peptidoglycan mesh looks likely. In *B. subtilis*, the essential L,D-endopeptidases CwlO and LytE could play a similar function. Both are cysteine peptidases, associated to the cell wall and required for cell growth, but active on L,D instead of D,D peptide bonds.

Participation of murein hydrolases in the elongation of the sacculus might have been hard to demonstrate, but their relevance for cell division has been undeniable for a long time. As a matter of fact, the most recurrently displayed phenotype in hydrolase mutants is a defective cell division. In both Gram-negative and Gram-positive bacteria, specific hydrolases (AmiA, AmiB, and AmiC in *E. coli*, LytA in *S. pneumoniae*, and Atl in *S. aureus*) are required for the resolution of the septal peptidoglycan. Impairment of the corresponding enzymes results in chained cells, which are unable to split their peptidoglycan septa to finish division. The cell division-specific hydrolases in *E. coli* are three N-acetylmuramyl-L-alanine amidases (AmiA, AmiB, and AmiC). All three are periplasmic proteins, and only AmiC shows a preferential location at the septum but exclusively in dividing cells. Amidases are potentially lethal hydrolases. To avoid the danger of autolysis, these proteins are activated exclusively at the division site by protein-protein interactions with the septum-associated proteins EnvC (activates AmiA and AmiB) and NlpD (activates AmiC). Similar mechanisms might be involved in the regulation of cell division associated hydrolases in other bacteria. Indeed, amidases are often associated to cell division in Gram-negative bacteria, and a factor (PcsB) similar to EnvC has been shown to play an important role in regulation of cell division in the Gram-positive *S. pneumoniae*.

Postinsertional Metabolism of Peptidoglycan

The sequence of events schematically presented earlier ends up with the incorporation of new peptidoglycan into the sacculus and the corresponding expansion of the later. But this is by no means the end of peptidoglycan metabolism. As a matter of fact, the sacculus is subjected to a constant, and complex, reorganization. At least three processes have been documented in the *E. coli* model system: maturation, turnover, and growth-state adaptation.

Peptidoglycan Maturation

Investigation of the evolution of new peptidoglycan as it ages indicates that new and old mureins differ to a considerable extent at least in *E. coli*, *B. subtilis*, and *Lactococcus lactis*. In the *E. coli* case, maturation is characterized by the elimination of the D-Ala at position 5 of the stem peptides, by a notable increase in cross-linking and a reduction in the mean length of peptidoglycan strands. The enzymology of maturation is still poorly understood. Low-molecular-weight PBPs are for sure involved, but the molecular identity of many of the activities suspected to intervene in the process remains unknown.

Peptidoglycan Turnover and Recycling

The phenomenon of murein turnover, that is, shedding of peptidoglycan muropeptides from the sacculus in the course of normal growth, was first described in Gram-positive organisms (*B. megaterium*, *B. subtilis*, *L. monocytogenes*, *S. aureus*, *Lactobacillus acidophilus*, etc.). Because most Gram-positive bacteria lack a permeability barrier external to the sacculus, turnover products are normally released into the growth medium, making detection a relatively straightforward matter. Demonstration in Gram-negative bacteria (*E. coli*, *S. enterica*, *N. gonorrhoeae*, and *Neisseria subflava*) took more effort because turnover is often coupled to very efficient recycling of the released muropeptides, which are transported back to the cytoplasm and then enter the biosynthetic pathway. The magnitude of the turnover process is variable from species to species and may depend on growth conditions. In most instances, it is quite relevant. Between 20% and 50% of total peptidoglycan is turned over each generation in those species where it has been measured as *E. coli* (30–40%), *B. subtilis* (50%), *B. megaterium* (50%), *S. aureus* (25%), and *N. gonorrhoeae* (20–50%). These high turnover rates mean that peptidoglycan has to be synthesized and incorporated into the sacculus at a rate considerably higher than growth rate. Turnover is often considered a requirement for cell expansion and to be associated to damage assessment and defense mechanisms.

Turnover is an enzymatically catalyzed process mediated by peptidoglycan hydrolases. The main turnover products in many Gram-negative bacteria are (1 → 6)-anhydro MurNAc-containing monomeric muropeptides, the product of lytic transglycosylases. In Gram-positive bacteria, turnover products are more diverse. In some like *B. subtilis*, turnover is mediated by a single hydrolase, a MurNAc-L-alanine amidase, but often shed out products that are the result of a more complete degradation of muropeptides involving several enzymes.

Interestingly, peptidoglycan turnover is important for virulence in some pathogens as *N. gonorrhoeae* and *Bordetella pertussis*. Both species have intensive turnover and release considerable amounts of GlcNAc-(1 → 6)-anhydro MurNAc-L-Ala-D-Glu-A₂pm-D-Ala, into the extracellular environment. This muropeptide has a strong cytotoxic action on ciliated epithelia and is identical to the tracheal cytotoxin of *B. pertussis* and the peptidoglycan-derived cytotoxin of *N. gonorrhoeae*. Furthermore, peptidoglycan fragments have strong immunogenic and mitogenic activities influencing the course of infection.

Turnover products are often recycled in particular in Gram-negative bacteria where released muropeptides accumulate in the periplasmic space. Several recycling pathways apparently exist. In *E. coli*, the major route for recycling is via the transporter protein AmpG, a transmembrane protein acting as a specific permease for intact muropeptides. AmpG transports GlcNAc-(1 → 6)-anhydro MurNAc-L-Ala-D-Glu-A₂pm, the main turnover product in this bacteria, to the cytoplasm. There, it is further degraded by a β-N-acetyl-glucosaminidase, which splits the disaccharide releasing GlcNAc and (1 → 6)-anhydro MurNAc-L-Ala-D-Glu-A₂pm, and a MurNAc-L-alanine amidase (AmpD), which breaks up the later fragment into (1 → 6)-anhydro MurNAc and the stem tripeptide. AmpD has a strict requirement for (1 → 6) anhydro MurNAc and therefore is inactive against the cytoplasmic precursors present in the cytoplasm as UDP-MurNAc-pentapeptide. Interestingly, the tripeptide released by AmpD is not further degraded. Instead, it is directly hooked onto a molecule of UDP-MurNAc by the enzyme Mlp (UDP-N-acetylmuramate:L-Alanyl-D-glutamate-meso-diaminopimelate ligase) in the presence of ATP. Although both Mlp and MurC add amino acids to UDP-MurNAc, they could neither compensate for each other nor accept each other peptide substrates. Mlp paralogs have been identified in other bacteria (*Haemophilus influenzae*), indicating that similar pathways could be widespread in bacteria.

Peptidoglycan recycling has been recently associated with the induction of chromosomal β-lactamases of the AmpC type in enterobacteria. β-Lactamases are the major bacterial defense mechanism against β-lactams. Enterobacterial AmpCs are inducible enzymes, and induction requires an operational peptidoglycan recycling pathway. The presence of antibiotics causes increased intracellular levels of (1 → 6)-anhydro MurNAc-L-Ala-D-Glu-A₂pm, which binds to AmpR, a regulatory protein of the *amp* operon, and induces synthesis of β-lactamase. Therefore, turnover and recycling might also play a sensory function to detect cell wall-damaging agents.

Adaptive Modifications of Peptidoglycan

The composition and structure of peptidoglycan change in response to environmental variations, in particular during the transitions in growth phase. Information is still limited to a few systems (*E. coli*, *S. enterica*, *H. pylori*, and *B. subtilis*), but it may well be a widespread phenomenon. Transition into stationary phase is a complex adaptive process, which involves a global reorganization of cell metabolism and very often specific morphological changes. In *E. coli*, transition into stationary phase triggers a full set of modifications both in the characteristics of peptidoglycan itself and in the complement of enzymes involved in peptidoglycan metabolism, PBPs, and peptidoglycan hydrolases. Compared with exponentially growing cells, peptidoglycan from stationary-phase *E. coli* is about 50% more cross-linked, has close to double amount of bound lipoprotein, and is made up of, in average, 30% shorter glycan chains. These modifications affect total peptidoglycan and are thought to require activity of specific enzymes. Interestingly, *E. coli* cells in the so-called 'viable but nonculturable' state, a condition thought to be clinically relevant in pathogenic bacteria, display similar alterations in their peptidoglycan. In *B. subtilis* peptidoglycan, cross-linking is also higher in stationary-phase cells. Increased cross-linking seems to be a rather general feature of nongrowing cells and has been detected in all cases studied.

Stationary-phase cells often display specific modifications in both biosynthetic and hydrolytic peptidoglycan enzymes. Activation of specific hydrolases is in fact thought to be critical for the induction of the autolytic response of many bacteria, as *S. pneumoniae*, to prolonged starvation and other adverse conditions as the presence of antibiotics.

Stationary-phase *E. coli* cells retain a considerable peptidoglycan biosynthetic activity. This activity is apparently associated to turnover and could account for renovation of about 20% of the cell peptidoglycan per hour. Interestingly, the class B PBP2 seems to be the key synthase in this process. The relevance of stationary-phase synthesis has not been asserted yet; however, an involvement in cell survival seems most likely.

Adaptation of *V. cholerae* to the stress conditions associated to media exhaustion includes a particularly sophisticated mechanism to modulate peptidoglycan synthesis. When conditions deteriorate, *V. cholera* synthesizes a periplasmic, broad specificity amino acid racemase (BsrV) in response to the activation of the main stress regulator RpoS. Synthesis of BsrV results in the production of D-amino acids, mostly D-Met and D-Leu, which are secreted to the medium reaching concentrations in the millimolar range. The production of D-amino acids results in their incorporation into the peptidoglycan where they substitute for one of the D-Ala residues, more frequently the one at position 4. Incorporation of the D-amino acids leads to decreased peptidoglycan biosynthetic activity. Mutational impairment of D-amino acid production results in osmotically unstable cells with excess peptidoglycan. Incorporation at position 4 occurs by an D-amino acid exchange reaction catalyzed by the L,D-transpeptidases responsible for (3 → 3) L,D cross-linkage and results in the release of the D-Ala residue normally found at that position and a muropeptide with a terminal residue of the new D-amino acid. D-amino acid incorporation at position 5 either might be the consequence of misincorporation of the D-amino acid into peptidoglycan precursors or could be mediated by an exchange reaction as mentioned earlier but mediated by D,D-peptidyl transferases. In the later case, the enzymes would transfer the peptide bond between the two D-Ala residues to the amino group of the foreign D-amino acid, releasing D-Ala and a muropeptide with the foreign D-amino acid at position 5. Such a capability has indeed been demonstrated for the class A PBPs of *E. coli*. Production of D-amino acids is not restricted to *V. cholera* and has been demonstrated in a number of unrelated bacteria (*B. subtilis*, *Aeromonas hydrophila*, *Yersinia enterocolitica*, *Streptomyces lividans*, and *Deinococcus radiodurans*). Furthermore, the demonstration of similar effects of D-amino acids in *B. subtilis* supports that comparable modulatory mechanisms might be relatively widespread.

Biophysical Properties of Peptidoglycan Sacculi

Thickness of Sacculi

As indicated before, bacteria fall in two broad categories, Gram-positive and Gram-negative, according to the organization of their cell envelopes. The former group displays a relatively thick peptidoglycan sacculus with covalently linked accessory polymers, while the later normally exhibits very thin sacculi devoid of accessory polymers. Precise measurement of the real thickness of sacculi has proved to be a rather complex task. Classical electron microscopy techniques had profound effects on the apparent thickness of sacculi in thin sections. Introduction of cryoelectron microscopy of frozen hydrated samples and atomic force microscopy recently led to a precise estimation of peptidoglycan thickness. In Gram-negative bacteria, results were unexpected because sacculi from *E. coli* and *Pseudomonas aeruginosa*, two species with identical peptidoglycan, gave different values. Cryoelectron microscopy of frozen hydrated cells gave peptidoglycan thickness values of 6.35 ± 0.53 nm for *E. coli* and 2.41 ± 0.54 nm for *P. aeruginosa*. Atomic force microscopy produced very close values, 6.0 ± 0.5 nm and 3 ± 0.5 nm for hydrated *E. coli* and *P. aeruginosa* sacculi, respectively. Concordance of both techniques is reassuring but clearly indicates that the three-dimensional organization of peptidoglycan in sacculi of Gram-negative bacteria is more variable than previously expected. Small-angle neutron scattering measurements indicate that in *E. coli*, the sacculus is not homogeneous in thickness; about 70% of total peptidoglycan is arranged in a monolayer, but up to 30% is in triple-layered domains. Unfortunately, the technique does not resolve the localization of the multilayered regions. Species-to-species variations in the abundance and distribution of multilayered regions could well explain the different apparent thicknesses in thin sections. In any case, these results seriously question the classical view of Gram-negative cell walls as a strict monolayer.

Sacculi from Gram-positive bacteria are undoubtedly multilayered and variable in thickness. Application of advanced techniques however revealed a bipartite organization of the cell wall. In all species studied, there is an inner zone of low density,

the inner wall zone, about 16 nm thick, apparently impoverished in polymeric materials, surrounded by the outer wall zone (OWZ) representing the polymeric peptidoglycan–teichoic acid complex. The OWZ is often in the 15–30 nm range but is quite variable.

Elasticity of Sacculi

Purified peptidoglycan sacculi behave like an elastic fabric. Available measurements indicate that surface of *E. coli* sacculi can reversibly expand and shrink by a factor of 3 without ruptures. Different approaches support the idea that sacculi are under dynamic stress in the living cell, expanding and shrinking in response to variations in turgor pressure. In the growing *E. coli* cell, sacculi appear to be stretched to about 140% of their surface at the relaxed (no turgor pressure) state.

The most interesting observation is the anisotropic character of elasticity in sacculi. Sacculi from rod cells are significantly more deformable along the longitudinal axis of the cell than in the transversal axis. Measurements in the atomic force microscope gave elastic moduli of 2.5×10^7 and $4.5 \times 10^7 \text{ N m}^{-2}$ in the respective directions (smaller elastic modulus means greater elasticity). These measurements are in agreement with the observation that changes in cell volume due to osmotic challenge are mainly due to elongation of the cells, while diameter remains nearly constant. In macromolecular peptidoglycan, peptide bridges can be stretched much further than the virtually inextensible glycan backbones. For this reason, elastic anisotropy is considered as a strong indication for a preferential orientation of the glycan strands perpendicular to the long axis of the cell. However, x-ray diffraction and infrared spectroscopy indicate that the sacculus is far from a regularly ordered structure. In fact, application of advanced electron cryotomography techniques permitted a direct visualization of peptidoglycan strands, roughly perpendicular to the longitudinal cell axis, encircling the cell in a disorganized hooplike distribution.

Permeability of Sacculi

Bacteria secrete numerous macromolecules that must necessarily cross the sacculus on their way to the external environment. Moreover, an assembly of supramolecular complexes spanning the cell envelope, as flagella or type III protein secretion systems, also have to deal with the presence of the sacculus. Therefore, it is relevant to know whether and how the structure of the sacculus, or the activity of particular enzymes, permits traffic and assembly of macromolecules.

Experimental data on the porosity of sacculi are scant and limited to *E. coli* and *B. subtilis*. Interestingly, pores in purified (relaxed) sacculi from both organisms are of similar average size, with estimated radii of 2.06 nm for *E. coli* and 2.12 nm for *B. subtilis*. This size limits free passage of globular proteins to molecular weights about 22–25 kDa in the relaxed state of peptidoglycan, which could go up to around 50 kDa for fully stretched sacculi. Bigger molecules could pass through the sacculus either in nonfolded or partially folded forms or through specialized mechanisms involving local peptidoglycan rearrangements. Assembly of supramolecular structures almost certainly requires such rearrangements. For instance, the flagellar rod has an average diameter of about 11 nm, much wider than peptidoglycan expected discontinuities. Participation of murein hydrolases in these rearrangements has been substantiated in a number of bacteria. In *C. crescentus*, the transglycosylase PleA is required for assembly of both pili and flagella at the cell pole. In *S. enterica* and *Rhodobacter sphaeroides*, flagellar proteins with muramidase activity (FlgJ) are required for flagellar assembly, which otherwise stalls at the M ring stage. Paralogs to hydrolytic enzyme genes have been found in operons coding for flagella, pili, and type III secretion systems, indicating that participation of peptidoglycan hydrolases in assembly processes might be a general mechanism.

Topological Heterogeneity in Sacculi

The existence in sacculi of peptidoglycan patches with different properties was first detected in *B. megaterium*. The polar caps of the rodlike cells were shown to turnover far more slowly than the lateral cell wall. More recently, it has been shown that the peptidoglycan at the polar caps of *E. coli* and *C. crescentus* sacculi is metabolically inert (IPG). That is, neither new precursors are inserted into these regions nor are they turned over. As a consequence, IPG has a very long life. As polar regions are the product of a previous septation event, IPG can be considered the final product of such a septation event. The mechanism underlying generation of IPG is unknown. Nevertheless, at least three proteins, PBP5, BolA, and FtsZ, have been shown to affect proper distribution of IPG in *E. coli*. All three proteins are involved in the morphogenetic pathway. Therefore, it seems that proper differentiation of IPG regions might be an important process for the cell. At present, no specific structural or chemical features have been found in IPG.

Concluding Remarks

The role of peptidoglycan as a reinforcement for the bacterial cell envelope was firmly established more than 65 years ago, and the basics of its structure and metabolism were worked out soon after. However, the full complexity of the bacterial sacculus became apparent only recently, hand in hand with the impressive advances in the field of bacterial division differentiation and morphogenesis. The structure once thought to be a rigid, and fundamentally inert structure, is showing a totally unexpected degree of complexity and dynamism at all imaginable levels. Furthermore, peptidoglycan is fast becoming an important player in unsuspected fields of bacterial biology, as pathogenesis, signaling, and ecology. Further research on the structural properties, biochemistry, and physiology of this fascinating macromolecule will undoubtedly help us to better understand bacterial life.

Glossary

Antagonism A biological type of interaction between living organisms that has a detrimental effect on one or both partners.

Biological control A process derived from antagonistic interactions between a beneficial organism and a pathogen or parasite that result in the control of a disease or pest.

Biopesticide A formulated active ingredient of biological origin, generally composed of microbial cells, that is used to control plant diseases or pests.

Biosafety The property of an active microbial ingredient related to the lack of adverse effects in plants and animals, including humans.

Competitive exclusion An ecological process by which an organism excludes another organism from a habitat through more efficient use of nutrients and space colonization.

Fermentation The mass production of microorganisms by cultivating in solid or liquid culture media for industrial purposes.

Formulation A method of preparing biopesticides for commercial delivery that consists of the preservation of microbial cells to increase shelf-life and enhance field survival and efficacy.

Registration The administrative procedure by which an active ingredient is authorized for commercial use following specific legal regulations.

Defining Statement

Microbial biopesticides are products made from beneficial microorganisms that are used to control plant diseases. Many products composed of bacteriophage, bacteria, yeast, and fungi are marketed worldwide, and are used by spraying or drenching plants, by local application of sticks or tablets near the root system, by seed coating or root bacterization before transplanting, and by using helper insects for dispersion.

The Plant As a Microbial Habitat

Microorganisms have adapted to the plant environment because plants offer a wide diversity of habitats, including the phyllosphere (aerial plant part), rhizosphere (zone of influence of the root system), and endosphere (internal transport system). Interactions may be neutral, beneficial, or detrimental for either the microorganism or the plant. Beneficial interactions for plants are caused by symbiotic or nonsymbiotic bacteria and by mycorrhizae, a highly specialized type of fungi, and have applications in plant phytostimulation, biofertilization, and bioremediation. Pathogenic or detrimental interactions of microbes with plants involve viroids, viruses, bacteria, and fungi, and lead to infectious diseases affecting only the plant kingdom.

The microbiota associated with plants has been classically studied by cultivation-dependent methods, which are estimated to recover only 0.01–10% of the total population. However, based on molecular analysis, it has been estimated that there are from hundreds to thousands microbial species per gram of soil in the rhizosphere or plant material in the phyllosphere.

Healthy plants contain a diversity of commensal and saprophytic microorganisms that contribute to provide, as in animals, an environmental equilibrium as the initial barriers for entrance of pathogens (Fig. 1). Bacteria are abundant in plants because they enable rapid growth. The Proteobacteria usually dominate samples in rhizosphere, particularly those of the α and β classes. Other major groups include Actinobacteria, Firmicutes, Bacteroidetes, Planctomycetes, Verrucomicrobia and Acidobacteria. In the case of phyllosphere, the dominant bacterial phylum are also the Proteobacteria (the α and γ classes), with Bacteroidetes and Actinobacteria also commonly found. The predominant genera are represented by the Gram-negative *Pseudomonas* (*Pseudomonas fluorescens*), *Pantoea* (*Pantoea agglomerans*, synonymous with *Erwinia herbicola*), *Xanthomonas* (*Xanthomonas campestris*), *Flavobacterium*, *Micrococcus*, and in some plants or plant parts by lactic acid bacteria (*Lactobacillus* and *Leuconostoc*) or *Azospirillum* species. Plants are also colonized by Gram-positive spore formers, which are mainly represented by the *Bacillus* species that colonize the soil and root system together with actinomycetes. Yeasts such as *Aureobasidium*, *Sporobolomyces*, *Cryptococcus*, *Torulopsis*, *Saccharomyces*, *Kloeckera*, *Rhodotorula*, and *Candida* are part of the microbiota of leaves and develop

[☆]Change History: July 2016. E. Montesinos and A. Bonaterra updated and made minor edits throughout the article; included some recent references on diversity of microbes associated to plants and beneficial microbes; updated Tables 1–3 and Fig. 7.

Fig. 1 Microorganisms interact with plant surfaces. (A) A print of a leaf on the surface of nutrient agar into a Petri plate reveals the presence of microbial colonies after several days of incubation; (B) infection of the stomata by a germinating spore of a pathogenic fungus; (C) colonization of the surrounding area of the stomata by bacteria; and (D) colonization of the hypanthia surface of a flower.

especially in fruits and flowers with high content of sugars. Different types of molds such as *Alternaria*, *Penicillium*, *Fusarium*, and *Aspergillus* can also be found. Several endophytic microorganisms also inhabit the phloem and xylem vessels of plants, and the intercellular apoplast and in dead or dying cells.

The composition and population levels of microorganisms in plants are determined by nutrient sources released by plant organs as root or leaf exudates or specific secretion systems as the nectaria in flowers. The degree of change in microbial composition is associated with the type of plant species or cultivar and varies according to the phenological state and organ (leaves, flowers, fruits, seeds, roots). Water availability on the aerial plant surface and temperature are environmental parameters that often exhibit strong fluctuations (daily, seasonal, hourly changes) and greatly affect microbial epiphytic life, as they determine growth rate, germination, taxis, and other essential processes for colonization of the plant surface. The root environment is more stable. The spatial distribution of the microbiota on the plant surface is not homogeneous because it depends strongly on suitable sites for colonization and growth. Microcolonies are often found in key environments like in the surrounding area of the stomata on the leaf surface, the nectaria in flowers, the calyx end in fruits, or the root tip.

Plant Disease and Biological Control Methods

Losses in crop production due to plant disease average from 13 to 15% worldwide and severely limit production, quality, and safety of food. Several thousands of diseases that are caused by 120 genera of fungi, 30 types of viruses, and 10 genera of bacteria have been described in plants.

Disease control is mainly achieved by treating crops with significant amounts of synthetic chemical pesticides. However, social and political concerns have influenced the practice of crop protection, which has been progressively reoriented toward a rational use of pesticides and toward a reduction in the number of registered active ingredients to those that are more selective, less toxic, and with a lower negative environmental impact. As a consequence, several countries have undertaken regulatory changes in pesticide registration requirements, given that consumer health and environmental preservation prevail over productive or economic considerations.

The therapeutic approach used in the past for plant protection is changing to a sustainable pest management approach. However, this change in crop protection methods is generating additional problems caused by a shortage of tools for control of

Fig. 2 The disease tetrahedron is composed of a susceptible host plant that can be infected by a virulent pathogen under suitable environmental conditions, and it is influenced by interactions with the natural microbiota. This four-level interaction may result either in the disease process in the plant host or in the biological control of the pathogen.

diseases in plants of economic importance. Fortunately, new methods of crop protection have emerged from traditional practices in agriculture and forestry such as the use of disease suppressive soils, crop rotation, soil solarization, and green manure or compost as organic amendments. Many of the benefits of these old techniques rely on naturally occurring microorganisms that exert a biological control on pests and diseases (Fig. 2).

Microorganisms Active in the Biological Control of Plant Pathogens and Their Mechanism of Action

Finding beneficial microorganisms to develop microbial pesticides is a trial-and-error process. The experience accumulated over several decades of research using different screening strategies indicates that many suitable sources come from disease-suppressive soils or healthy plants in epidemic areas affected by a given disease. However, success has also been obtained with nondirected search, that is finding microorganisms of interest from habitats far from the plant environment intended to be protected.

To be a biological control agent is not an attribute of a given genera or species of microorganisms, but it is generally restricted to the strain level. Usually, a few out of the thousands of strains that have been isolated result in a good candidate being developed as a commercial biopesticide. Many research projects have been successful and hundreds of strains of microorganisms have been reported as active in the control of plant pathogens, such as bacteria and fungi causing aerial or root diseases, or are effective against postharvest rot of products like fresh fruits and vegetables. Strains of biological control agents are distributed among Gram-negative bacteria of the families Rhizobiaceae, Pseudomonadaceae, and Enterobacteriaceae, and among Gram-positive bacteria such as Bacillaceae, Lactobacillaceae, Leuconostocaceae, and Streptomycetaceae. There are also representatives of yeasts and fungi within Ascomycota and Basidiomycota, and also in Oomycota. Finally, there are also hypovirulent pathogens with biocontrol ability like *Fusarium*, *Rhizoctonia*, *Sclerotinia*, and *Phytophthora*, mainly isolated from suppressive soils (Table 1).

Beneficial microorganisms able to control plant diseases can colonize or compete with the pathogens for nutrients and sites of interaction with the plant host, or exert antagonism through antimicrobial compounds, develop hyperparasitism or directly attach to the pathogen cells, interfere with pathogen signals, or induce resistance into the plant host. There are examples of strains that cover a single mechanism, or it is possible that a combination of several mechanisms converge within the same strain (Table 2; Figs. 3 and 4). Antibiosis against plant-pathogenic bacteria and fungi is very common among bacterial pesticides, for example, by the production of opines, a type of toxic derivative of amino acids, in *Agrobacterium radiobacter*, phenolic antifungal compounds in *Pseudomonas* species, antimicrobial peptides and polyenes in *Bacillus* and actinomycetes, or lytic enzymes in several yeast and fungi like *Candida* and *Trichoderma*. Competitive exclusion of the pathogen from sites of infection by better use of nutrients and colonization is also a common mechanism that can accompany other mechanisms. Several hyperparasites, especially abundant among the yeast and fungi biocontrol agents like *Coniothyrium*, *Gliocladium*, *Pichia*, *Ampelomyces*, *Streptomyces*, and *Trichoderma*, interact directly and degrade the fungal cell wall or spore envelope of pathogens. Some bacteria and fungi

Table 1 Groups of microorganisms that have strains of biocontrol agents of plant diseases

Group	Family/Class	Genus
Virus	–	Bacteriophages Weak strains plant viruses
Bacteria	Bacillaceae Paenibacillaceae Cellulomonadaceae Enterobacteriaceae Lactobacillaceae Leuconostocaceae Pseudomonadaceae Rhizobiaceae Streptomycetaceae Xanthomonadaceae	<i>Bacillus</i> <i>Brevibacillus</i> <i>Paenibacillus</i> <i>Cellulomonas</i> <i>Enterobacter</i> <i>Pantoea</i> (<i>Erwinia</i>) <i>Rahnella</i> <i>Serratia</i> <i>Lactobacillus</i> <i>Leuconostoc</i> <i>Burkholderia</i> <i>Pseudomonas</i> <i>Agrobacterium</i> <i>Streptomyces</i> <i>Lysobacter</i>
Yeast	Ascomycota Basidiomycota	<i>Aureobasidium</i> <i>Candida</i> <i>Coniothyrium</i> <i>Debaryomyces</i> <i>Kloeckera</i> <i>Metschnikowia</i> <i>Pichia</i> <i>Saccharomyces</i> <i>Cryptococcus</i> <i>Pseudozyma</i> <i>Rhodotorula</i> <i>Sporobolomyces</i>
Fungi (molds)	Ascomycota Basidiomycota Oomycota	<i>Ampelomyces</i> <i>Aspergillus</i> <i>Chaetomium</i> <i>Epicoccum</i> <i>Gliocladium</i> <i>Muscodora</i> <i>Myrothecium</i> <i>Penicillium</i> <i>Trichoderma</i> <i>Ulocladium</i> <i>Verticillium</i> <i>Phlebiopsis</i> <i>Pythium</i>

are able to induce defense responses in plants, by producing either elicitors (eg, cell wall components) or messenger molecules (eg, salicylic acid). Finally, a mechanism has emerged based on the finding that there are bacteria that can degrade chemical signal messengers necessary for quorum sensing (eg, acyl homoserine lactones) used by many plant-pathogenic bacteria to start the infection process in the host.

The basic and applied research on biological control agents has stimulated sequencing of their genomes. Some of the genomes that have been completely sequenced for various biological control strains are *Bacillus amyloliquefaciens* FZB42, Y2, and M27, *Bacillus pumilus* INR7, *Bacillus subtilis* 168 and XF-1, *Brevibacillus laterosporus* B9, *Pantoea vagans* C9-1 and *P. fluorescens* (*P. protegens*) Pf-5, CHA0 and Cab57. In the case of yeast strains, the genome sequence is available for *Debaryomyces hansenii* CBS767, *Cryptococcus flavescentis* OH182.9-3C and *Pichia guilliermondii* and in the case of fungi *Pythium oligandrum* Po37, *Trichoderma gamsii* T6085, and *Trichoderma harzianum* T6776.

Table 2 Mechanisms of action in selected biocontrol agents of plant diseases

Microorganism and strain	Target pathogen or disease	Mechanism involved
Virus		
Bacteriophage	<i>Xanthomonas</i> , <i>Pseudomonas</i> and <i>Ralstonia</i> diseases	Lysis

<i>P. syringae</i> ESC10/ESC11	Postharvest rot fungi	Ab-Syr, CE Ab-pseudopeptide
<i>Pantoea vagans</i> C9-1	Fire blight	CE, HP, Ab-polyenes
<i>Streptomyces griseoviridis</i> K61	Soil-borne pathogens	
Fungi		
<i>Ampelomyces quisqualis</i> AQ10	Powdery mildew	HP
<i>Aureobasidium pullulans</i> CF10	Postharvest fungi, fire blight	CE, Ab
<i>A. pullulans</i> Ach1-1	Postharvest fungi	CE
<i>Candida oleophila</i> I-182/Q	Postharvest fungi	CE, Ab-lytic enzymes
<i>Candida sake</i> CPA-1	Postharvest fungi	CE
<i>Coniothyrium minitans</i> CON/M/91-08	Fungi	HP
<i>Gliocladium catenulatum</i> J1446	Soil-borne fungal pathogens	HP, Ab-lytic enzymes
<i>Gymnopleurus virens</i> GL21	Soil-borne fungal pathogens	HP, Ab-gliotoxin
<i>Pichia guilliermondii</i> 87	Fungi	CE, HP
<i>Trichoderma harzianum</i> T22, P1	Soil-borne pathogens	COM

Abbreviations: Ab, antibiosis; AMP, cyclic antimicrobial peptides; CE, competitive exclusion; COM, complex; DAPG, diacetyl phloroglucinol; DDR, dihydro-rhizoxin; HP, hyperparasitism; IR, induced resistance; PCA, phenylcarboxylic acid; Plt, pyoluteorin; Prn, pyrrolnitrin; SYR, syringomicin.

**Fig. 3** An overview of the mechanisms of biological control of plant pathogens that have been demonstrated in beneficial microorganisms interacting with plants.

Fig. 4 Antagonism against plant pathogens can be revealed in vitro. (A) Halus of inhibition of confluent growth of a fungus produced by colonies of selected antagonistic bacteria and yeast. (B) Antibiosis is accompanied by swarming motility of the colonies of the antagonist bacteria against a plant-pathogenic bacterium. (C) Production of lytic enzymes that hydrolyze chitin, a component of the fungal cell wall that has been added to the agar plate. (D) Synthesis of siderophores around colonies that are involved in competition for iron. (E) and (F) Direct interference and hyperparasitism due to attachment of bacterial cells to the spores of fungi.

Discovery of Microbial Pesticides

The process of discovery and development of a microbial biopesticide consists of two stages. The first stage deals with the isolation of candidate microorganisms in pure culture, the identification and characterization of strains, and the measurement of efficacy in laboratory-controlled bioassays to finally perform pilot testing under greenhouse or field conditions. In the second stage, candidate microorganisms are cultivated at a large scale, preserved and formulated for industrial production, and submitted for toxicological and environmental impact studies to qualify for registration and authorization for commercial delivery (Fig. 5).

Finding bacteria, fungi, or virus able to interfere with the biological cycle of selected plant pathogens requires proper sampling to increase the probability of obtaining useful strains. For this reason, samples are taken at places or containing materials where there is evidence of beneficial microorganisms, such as in disease-suppressive soils or healthy plants or plant parts that survived the disease in epidemic areas.

The screening for antagonistic activity against the target pathogen is a critical step because the type of microorganism selected depends on the method used. Approaches based on host-mediated selective enrichment and phenotypic or molecular

Fig. 5 Steps involved in the discovery of microbial pesticides that ends up with patent filing and registration and authorization for commercial delivery of formulated products.

marker-assisted selection have improved the isolation and development of new biocontrol agents. Usually, screening procedures are specific to a given mechanism of action, such as antibiosis, competition, or induction of plant defenses. Isolation in pure culture needs a suitable method of cultivation in synthetic media or of enrichment in a given biological system (cell cultures or trap organisms).

At this stage, several hundreds or thousands of isolates are collected, and after identification the strains are submitted for efficacy bioassays in a small-scale controlled laboratory environment using *in vitro*, *ex vivo*, or, *in planta* tests in three-partner model pathosystems (putative biological control agent, target pathogen, host plant) (Fig. 6). The knowledge of the mechanisms of action of a biological control agent and the information derived from partially or totally sequenced genomes can provide data on gene targets that can be used for high-throughput screening procedures. Modern techniques of assisted selection using phenotypic or genotypic markers contribute to improving the productivity of the screening stage. Advances in DNA arrays or screening of metagenomic libraries of cloned DNA can also contribute to developing potent screening methods. During the selection process, apart from efficacy and consistency of results between bioassays, additional criteria, such as the presentation of a low effective dose, the production of specific metabolites against the target pathogen, and tolerance to some pesticides commonly used in agriculture, are used to retain isolates.

Pilot tests are conducted under conditions as close as possible to the environment under which biological control will be practiced. During this stage, the biocontrol agent is confronted with several pathosystems to verify its action spectrum and under environmental conditions sufficiently diverse to guarantee a wide range of applicability. The high number of different conditions to be tested permit working with only those isolates that were selected as suitable candidates in the previous massive screening stage. Unfortunately, work on most biological control agents discovered concludes with this step because of a too narrow action spectrum, inconsistency of results between trials, or a low efficacy under field or practical conditions (Fig. 7).

The discovery of biopesticides based on microorganisms, if successful, is of economic interest because of the possibility of commercial exploitation of the technology. Several hundreds of patents exist involving strains of microorganisms with potential application as microbial pesticides, including fungicides, insecticides, herbicides, and plant growth stimulants.

Production and Formulation

For the commercial development of a microbial pesticide, the microorganism cells have to be produced at the industrial scale, preserved, and formulated for storage and delivery. Depending on the nature of the microorganism (bacteria, fungi, yeast, or

Fig. 6 Pathogen infection in a plant host is controlled by microbial pesticides. (A) Inhibition of brown spot infections on pear leaves that have been treated with an antagonistic bacterium (upper left panel) in comparison to a non-treated control (lower left panel). (B) Control of fire blight infections in immature pear disks by several strains of antagonistic bacteria (rows). (C) Inhibition of fungal infections in strawberry roots by antagonistic bacteria (upper right panel) in comparison to a non-treated control (lower right panel). (D) A pear fruit wounded, treated with antagonistic bacteria, and inoculated with spores of the blue mold shows strains that inhibit rot.

virus), the methods used for industrial scale-up are solid- or liquid-phase fermentation. Methods consist essentially of the technology used in the pharmaceutical and food industry. Bacteria and yeast are produced by liquid fermentation using bioreactors, but many fungi are fermented by using solid-state procedures. The objective is to obtain the highest yield possible using a culture medium with the lowest cost, often achieved using food-grade molasses, peptones, brewer's yeast extract, and protein hydrolysates for industrial use. After liquid fermentation the microbial cells are concentrated by filtration or centrifugation, and in solid fermentation the material is recovered and homogenized to get a concentrated liquid suspension of cells or spores. In cases in which the microorganism is not directly culturable in synthetic media (bacteriophage), industrial production consists of an initial step in which the host bacterial cells are produced and a second step of virus scale-up feeding on the previously produced bacteria. Concentrated suspensions obtained generally range from 10^8 to 10^{10} cfu mL⁻¹, depending on the nature of the microorganism (Fig. 8).

The storage and preservation of the microbial pesticide to increase its shelf-life is one of the main limiting factors for commercialization. The procedure involves stabilizing the viability of cells in a liquid-phase suspension maintained under refrigeration or frozen in the presence of cryoprotectant substances, or as a dehydrated product. Dehydration is the best from a practical point of view because it permits optimum storage conditions, handling, and distribution. Lyophilization is a method that can maintain better viability, but the cost is very high. Encapsulation of microbial cells is also used, in which the cells are mixed with a matrix-forming material such as gelatinized polysaccharides or emulsified in a lipid material that is finally diluted and spray-dried to obtain the desired particles. At the industrial level and in order to obtain a low-cost product, the method preferred is spray or fluidized bed drying. However, spray drying produces a high loss of viability in some microorganisms (eg, Gram-negative bacteria) due to the thermal treatment that accompanies the process. Although many microbial pesticides are prepared as dried products, some are delivered as liquid suspensions of cells or spores. Irrespective of whether the final preparation is aqueous or dried, the active ingredient is formulated to obtain a marketable product. The formulations are composed of an active ingredient (microorganism cells or spores and sometimes culture components), carriers or inert materials used to support and deliver the active ingredient to a target, and adjuvants that promote and maintain the functionality of the active ingredient by including nutrients, chemical agents that filter ultraviolet light radiation, or osmoprotectant compounds that prevent damage from cell desiccation. However, care must be taken because certain components in the formulation can stimulate the pathogen and promote disease. In many cases, the technology for formulating biopesticides is similar to that used for formulating chemical pesticides and pharmaceutical products, and results in stable and active products for several months.

Liquid formulations contain around 10^7 – 10^9 cfu mL⁻¹, whereas powdered products have the active ingredient generally at a higher concentration (around 10^9 – 10^{10} cfu g⁻¹ for bacteria and yeast), but can be lower in certain fungi. The method of application depends very much on the pathosystem to be controlled. Spraying or drenching plants is a common practice when using an inundative approach of control. However, inoculative or augmentative strategies consist of preparing sticks or

Fig. 7 Control of blue mold rot in apples (a), brown rot in peach (b) and potato root-rot disease (c) with antagonistic bacteria. Nontreated controls are shown on the left side and treated fruits on the right side.

immobilizing systems (alginate beads) and seed coating or bacterization of the root system in seedlings before transplanting. Inundative application methods are essentially the same as used for chemical pesticides. In this strategy, the dose of biocontrol agent has an important effect on the efficacy of control, because the latter depends on the relative amounts of pathogen and biocontrol agent. For many microbial pesticides, the median effective dose (ED₅₀) is in the range of 10^6 – 10^7 cfu mL⁻¹ for bacteria and 10^5 – 10^6 cfu mL⁻¹ for fungi and yeast. The ratio between cells of the biocontrol agent and cells of the pathogen for optimum control has been used as a measure of efficiency, which ranges in value from one to several hundreds. The efficiency of biocontrol is also dependent on pathogen aggressiveness and host supportiveness. Therefore, to ensure covering a wide range of conditions of applicability in practice, a dose of around 10^8 cfu mL⁻¹ is recommended for bacterial biocontrol agents and 10^7 for fungi or yeast. Accordingly, formulated products are diluted in nonchlorinated water to get the dose recommended.

Fig. 8 Industrial production of microbial pesticides consists of scaled-up fermentation of a suitable strain, downstream processing of the biomass and supernatant of cultures, and formulation for commercial delivery.

Monitoring, Environmental Impact, and Biosafety

Specific analysis of the microorganism strain of the biopesticide is necessary for quality control during production and formulation and also to perform studies on traceability, residue analysis, and environmental impact. In field studies, the classical microbiological methods may not be suitable because they do not distinguish the strain that contains the microbial pesticide from the same species that could be present in the natural microbiota associated with plants. In certain cases, selecting an spontaneous mutant resistant to a suitable antibiotic for which it is rare to find resistance in nature is sufficient. However, genotypic markers are preferable because they are more stable and their expression does not depend on the type of culture media used for analysis. Specific genotypic markers can be found by DNA fingerprinting of the biocontrol agent strain, based on the amplification of gene sequences by PCR methods (RAPD, REP, ERIC, AFLP), or by digesting DNA with restriction enzymes (RFLP, PFGE). Genome sequencing is currently the best option due to the decrease in cost and the possibility to analyze several strains of the same species. The comparison of genome sequences and fingerprinting patterns of the biocontrol strain with those of a wide collection of representative strains of the same species can identify specific regions or bands that can be sequenced and characterized (SCAR fragments). The knowledge of the nucleotide sequence of SCAR fragments can aid in the design of primers for PCR analysis. Real-time PCR (quantitative PCR) is a powerful tool for developing methods of highly specific quantitative analyses of strains of the active ingredient in microbial pesticides under natural conditions.

Another important issue that has to be taken into consideration in microbial pesticides is biosafety. Biosafety is necessary to avoid nontarget effects on plants or animals, or on the environment, because the isolation of a given microorganism from plants is not a proof of its innocuity. Toxicological studies in mammals, including acute toxicity tests, are performed to guarantee safety to consumers and handlers of the microbial pesticide, especially if cases of opportunistic infections reported at the clinical level or if certain secondary metabolites of concern are produced. However, risk evaluation is not a simple task, because the risk of non-target effect by a given microorganism is estimated from the intrinsic toxicity–pathogenicity level, the degree of exposure, and the susceptibility of the possible receiver. Most microbial pesticide strains meet all biosafety rules. However, in a few cases, there are uncertainties regarding the potential risk, because human isolates reported in clinical opportunistic infections are not distinct from environmental isolates. There is scientific controversy regarding the use of strains of *Burkholderia cepacia*, *Pseudomonas putida*, and *P. agglomerans*, as biological control agents, which will need further studies of safety and toxicological risk. Interestingly, some of these microorganisms are part of the normal microbiota found in plants and are present in several plant-derived fresh products. These uncertainties are the reason for specific and differing regulations on risk classification of microorganisms among countries.

Registration and Commercialization

Approval of microbial pesticides for commercialization requires detailed dossiers accounting for scientific data on microorganism identity, biological properties, efficacy, specific analytical methods, residues, traceability, and potential adverse effects on human health and nontarget organisms. In the European Union, the registration and authorization of microbial pesticides as plant protection products depends on the Health and Food Safety Directorate, and is regulated by the Directive 2009/128/EC and the regulation 1107/2009/EC. In the United States, authorization is regulated by the Environmental Protection Agency. Furthermore, specific requirements may change when an authorization application considers the microorganism as a biocide or a plant enhancer. Therefore, the availability of commercial biopesticides depends on the specific regulations in each country, but several products that include bacteriophage, bacteria, yeasts, and fungi, which are active against a wide range of plant pathogens in very diverse crops and agroclimatic conditions, are marketed (Table 3).

Table 3 Some examples of commercial microbial pesticides

Active ingredient	Commercial name	Target pathogen/disease	Host
<i>Agrobacterium radiobacter</i>	Nogall, Galltrol-A	Crown gall	Fruit and nut trees, ornamentals
<i>Ampelomyces quisqualis</i>	AQ10	Powdery mildew	Apples, cucurbits, grapes, ornamentals, strawberries, tomatoes
<i>Aspergillus flavus</i>	AF36 ^a , Aflaguard, NRRL21882 ^a	<i>A. flavus</i>	Cotton, peanut, corn
<i>Aureobasidium pullulans</i>	Blossom protect	Fire blight	Pome fruits
<i>Bacillus licheniformis</i>	Green releaf ^a , 145F ^a Ecoguard	Several fungal diseases of seedlings	Ornamental plants, conifers and tree seedlings, ornamental turf
<i>Bacillus mycoides</i>	BmJ	<i>Cercospora beticola</i>	Sugar beet
<i>Bacillus pumilus</i>	Ballad, Yield shield ^a , Sonata	Soil-borne fungi, powdery and downy mildew, early and late blight, brown spot,	Soybean, cucurbits, grapes, hops, vegetables, peanuts
<i>Bacillus subtilis</i>	Serenade, Rhapsody, Biopro ^a , BS-F4, Promix, Subtilex, HiStick N/T, Companion, Kodiak ^a , Clarity, Cease	Bacteria (fire blight) and fungal root diseases, <i>Alternaria</i> , <i>Aspergillus</i> , gray mold	Grape, hops, vegetables, peanuts, pome and stone fruits, soybean, alfalfa, cotton
<i>B. subtilis</i> var. <i>amyloliquefaciens</i>	Taegro, Tae-Technica ^a , Double Nickel, Bacstar	Soil-borne fungal rots, Fire blight	Greenhouses shade and forest tree seedlings, ornamentals, and shrubs
<i>Bacteriophage</i>	Agriphage	Bacterial blight and spot	Tomato, pepper
<i>Candida oleophila</i>	Aspire ^a , Nexy ^a	Postharvest fungal rot	Citrus and pome fruits
<i>Coniothyrium minitans</i>	Contans, Koni ^a	<i>Sclerotinia</i>	Vegetables, canola, oilseed rape, sunflower, soybean
<i>Cryptococcus albidus</i>	Yield plus	Postharvest fungal rot	Pome fruits
<i>Gliocladium</i> sp.	Gliomix	<i>Rhizoctonia solani</i> , <i>Pythium</i>	Vegetables and turf
<i>Gliocladium catenulatum</i>	Primastop ^a , Prestop	Soil-borne fungal pathogens	Ornamental, vegetable, and tree crops
<i>Gliocladium virens</i> (<i>Trichoderma virens</i>)	Soilguard	Soil-borne root fungal diseases	Ornamentals and food crops in greenhouses and nurseries
<i>Metschnikowia fructicola</i>	Shemer	Fungal rot	Preharvest and postharvest fruits
<i>Pantoea agglomerans</i>	Bloomtime, Blossom bless,	Fire blight	Pome fruit trees, ornamentals
<i>Pantoea vagans</i>	Blightban C9-1 ^a	Fire blight	Pome fruit trees, ornamentals
<i>Phlebiopsis gigantea</i>	Rotstop	<i>Heterobasidion annosus</i>	Coniferous trees
<i>Pseudomonas aureofaciens</i>	Spot-less ^a	Antracnosis	Turfgrass
<i>Pseudomonas chlororaphis</i>	AtEze ^a , Cedomon, Cerall	Soil-borne fungi	Greenhouse crops and cereals
<i>Pseudomonas fluorescens</i>	Blightban A506	Fire blight, frost damage	Fruit trees, almond, potato and tomato crops
<i>Pseudomonas syringae</i>	Biosave10 LP, Biosave 11 LP, Esc-10 ^a	Postharvest fungal rot	Pome fruits, citrus, cherries and potatoes
<i>Pseudomonas</i> sp.	Proradix	Fungal and bacterial diseases	Potatoes
<i>Pseudozyma flocculosa</i>	Sporodex ^a , Pseudozyma ^a	Powdery and downy mildew	Greenhouses roses and cucumber
<i>Pythium oligandrum</i>	Polyversum, DV74 ^a	Soil-borne pathogenic fungi	Food crops, ornamentals and turf
<i>Streptomyces griseoviridis</i>	Mycostop	Root rot, gray mold and foot decay	Ornamental and vegetable crops
<i>Streptomyces lydicus</i>	Actinovate	Root rot, gray mold and damping-off	Greenhouse and nursery crops, turf

(Continued)

Table 3 Continued

Active ingredient	Commercial name	Target pathogen/disease	Host
<i>Trichoderma asperellum</i> and <i>Trichoderma gamsii</i>	Asperello, Biotam, Bioten, Radix, Remendier, Tenet	Fungal diseases	Greenhouse crops
<i>Trichoderma harzianum</i>	Binab T, Trichopel, T-22, Rootshield, PlantShield, Tusal, Trichodex ^a , BiodermaH/Barrier	Root rot, gray mold and damping-off	Trees, shrubs, transplants, ornamentals, vegetables
<i>Trichoderma polysporum</i>	BinabT	Fungal infections through wounds	Ornamentals, shade, and forest trees
<i>Trichoderma viride</i>	Bioderma/Protector	Fungal diseases	Cotton, Cereals, Pulses, Vegetables, Oilseeds, Fruit
<i>Ulocladium oudemansii</i>	Botry-zen	Gray mold	Grape
<i>Verticillium dahliae</i>	Dutch Trig	Dutch elm disease	Elm

^aRegistered but currently not commercialized biopesticides.

Phage Therapy

A Bacterial Problem

Behind cardiovascular disease and cancer, infectious diseases are the third leading cause of human mortality. Civil engineering, vaccination, and antibiotic therapy, the trinity of antibacterial technologies, are directly correlated with a reduction in the worldwide impact of infectious diseases. But there is concern heading into the future about the continued effectiveness of these measures at lowering morbidity and mortality. First, the rise of antibiotic resistance has reached a tipping point. There are strains resistant to most if not all clinically prescribed antibiotics, including recently approved versions. The development of new antibiotics has not kept pace with the evolution of resistance. As a result, leading health organizations project that by 2050 millions of people will succumb to previously preventable infections, and at staggering costs.

Second, a flurry of successful vaccine approaches developed in the middle of the 20th century, mostly centered on the use of bacterial toxins to induce adaptive immunity, have made little progress in recent times. The “one-toxin, one-disease” paradigm may not be true for some bacterial species that demonstrate multiple virulence mechanisms and readily engage in the horizontal transfer of virulence genes. Thus, vaccines that demonstrate universal efficacy against multiple strains of the same species might not be feasible unless these strains share common virulence mechanisms.

Third, the recent emergence of the role of the microbiome in inflammation and chronic diseases, including those not historically thought of as having an infectious etiology, implies that even civil engineering approaches alone are unlikely to further reduce carriage of disease-inducing bacteria. Most of these microbes live in and on us, making sterilization all but impossible; and, many of them are adapted to the human immune system, thereby making vaccination more challenging.

These three facets, when considered as pieces of a larger problem, imply “outside the box” antibacterial approaches will be necessary to make further gains in the war on bacteria. One such approach is the use of phage, natural-born killers of bacteria, to destroy problematic strains. Phage may be the most diverse, and numerous, of any self-replicating entity on Planet Earth, representing an essentially unlimited supply. They too can quickly evolve and in clinically-relevant time frames. Thus, new strains of antibiotic resistant or virulent bacteria that emerge, perhaps strains where vaccination might not be realistic, can be killed with new strains of phage. Because phage can be targeted to a specific bacterial host, their use in “editing” the human microbiome to rid undesirable bacteria, either from the intestine or skin, may also prove useful in reducing bacterial burden in high risk individuals. Phage can (and are) used in agriculture and food processing to eliminate bacterial pathogens. Thus, they may spare the use of excess antibiotics, thereby decreasing resistance. The history of phage therapy is one of highs and lows. Only recently have researchers attempted to define the limits of these amazing antibacterial machines in models of infection.

What Is a Phage?

Any treatment of the topic of phage therapy should first begin by defining phages, their mechanisms of bacterial destruction, where we find them, and how they are isolated. If phage are to become commonplace in the worldwide clinical sector, not only will this knowledge be needed by healthcare personnel, the details of these properties will shape their regulation and use.

First and foremost, phage are replicating viruses that house nucleic acid in their proteinaceous head. This nucleic acid must be injected into the bacterial cytoplasm. There it encodes the proteins necessary to make new phage progeny. The progeny are released after the bacterial cell is lysed, a step induced by the phage proteins themselves. Phage that lyse bacteria immediately after the assembly of new phage in the cytoplasm are called lytic phage. Lytic phage are best exemplified by T4 (Fig. 1). The other component of the phage, the tail, is responsible for engaging the bacterial surface. This usually occurs via the binding of phage proteins at the end of the tail, called tail fibers, to specific receptors on the bacterial surface. After binding, the nucleic acid in the phage head is squeezed through the tail like a plunger pushing fluid through a syringe. The process of engaging the bacterium in a way that leads to injection of the nucleic acid into the bacterial cytoplasm is termed adsorption. The injected nucleic acid encodes all proteins needed to make new phage, including head and tail proteins, polymerases, and other accessory factors needed for assembly and enzymatic function of each phage-packaging step. After new phage are produced in the bacterial cytoplasm, specific protein holins and lysins, also encoded by the phage, begin to degrade the bacterial membrane and peptidoglycan, respectively, often referred to as “lysis from within.” When considering phage therapy, the events that result in a production infection and death of the bacterial cell are critical.

Lytic phage contrast with what are termed lysogenic phage, best exemplified by lambda (λ). Following infection, lysogenic phages integrate their genome into the bacterial chromosome, a process called lysogeny. The phage genome then replicates along

*These authors contributed equally to this work.

with the bacterial genome every time the bacterium divides. The phage at this point is referred to as a prophage. The prophage can, under very specific conditions, excise its nucleic acid out of the bacterial genome, make phage progeny, and generate a lytic event to release the new phage. In general, lysogenic phage should be avoided in phage therapy, for reasons discussed below, but mainly because their infection too infrequently leads to lysis of the bacterial cell. Finally, it is possible for phage to induce bacterial cell lysis at high multiplicities of infection. The overproduction of lysins during multiple adsorption events leads to bacterial lysis without productive infection, a process termed “lysis from without.”

Phage are everywhere. Estimates of their total abundance on Earth includes the number one with greater than 30 zeroes after it, making it the most numerous replicating entity on the planet. A general rule of thumb is that wherever bacteria are found, so too will phage. They are present in high concentrations in puddles of water, the soil, ponds and lakes, and even growing vegetation. They are in the air, being lifted by strong winds on dust particles. Even man-made objects can have phage on their surface, especially if they come into contact with people. Our own gastrointestinal tract is rich in phage; human stool, as a component of usually sewage, is often a source of new phage, especially those targeting human-adapted bacteria. Even treated tap water can have millions of phage in a single glass. The constant exposure to phage in all aspects of our life means that we are well adapted to them.

For many phage, their isolation is inexpensive and not technically challenging. This is one of their remarkable properties. What might amount to a few hundred dollars in material costs, a purified and highly active phage preparation can be attained in about a week's worth of time. The process begins by identifying a source. Not all sources contain the phage one might be interested in, so it is important to have an idea of the type of bacterium you want to infect. For example, bacterial pathogens that commonly infect the human gastrointestinal tract, such as shigella, salmonella or *Escherichia coli*, are common in human and animal stool, or the environment where human waste may run off. Thus, phage that efficiently kill these bacteria are highly abundant in these sources. A sample is usually collected, mixed with an appropriately buffered solution, and the bulk material pelleted. The resulting supernatant is often passed through a filter that will retain most sizable particles and cells but allow the smaller phage to pass through. This filtrate can next be added to an agar lawn of a test bacterium that is likely to support an infection (from the sewage example above, it may be *E. coli*), and the next day the plate is examined for plaques. A plaque is a circular clearing of the cloudy bacterial lawn in the area where the filtrate was applied. It suggests a phage in the filtrate lysed the bacteria on the plate, creating a zone of clearance, analogues to the same effect observed with antibiotics. Plaques can then be scraped into a fresh culture of growing bacteria which amplifies the number of phage progeny trillions of fold. These released phage can then be further purified using density gradient ultracentrifugation to yield high-titer preparations with efficient killing activity.

Fig. 1 The phage life cycle. The stages of phage infection are shown for both lytic and lysogenic phages. Phage products can also be used to lyse bacterial cells and themselves may constitute viable antimicrobials.

Phage Therapy: A History

(i) The Classical Years (1915–1942): Discovery and Early Hope

Phage therapy represents the therapeutic use of viruses to treat bacterial infections. Bacteriophages were likely first described in 1896 by British scientist Ernest Hankin. In Hankin's published work in the *Annals of the Pasteur Institute*, he reported that some biologicals found in the Ganga and Yamuna rivers in India had the capacity to kill cholera-inducing bacteria. Whereas it is not known for sure if Hankin was describing phage (he did not isolate these biologicals), the idea that environmental sources contained antibacterial activity was enticing. Almost two decades later, William Twort (1915) and Félix d'Herelle (1917) independently discovered what we now know as bacteriophages. Twort attempted to follow Koch's postulates to isolate the antibacterial activity and demonstrate they maintained their bacterial killing ability in a new culture. D'Herelle, a French-Canadian microbiologist, isolated bacterial viruses from stool samples of patients who suffered from shigellosis. He demonstrated that these viruses were able to lyse *Shigella* in culture media, and coined the term "bacteria-eaters" or bacteriophages. Further, he treated shigellosis with phage in animal subjects, the first attempt at phage therapy. The discovery of phage spawned a new era of microbial research (Fig. 2).

D'Herelle continued his research into bacteriophages and traveled the globe popularizing these new findings. In 1919, a field trial using phages against *Salmonella gallinarum*, which causes avian typhosis, was performed in France. In the early 1920s, there were case reports of the administration of phage in the US to treat chronic furunculosis. The pharmaceutical company Eli Lilly developed a phage preparation to treat *Streptococcus* and *Bacilli* infections. D'Herelle's work led him to cofound with George Eliava an institute (which bears Eliava's name) in what is now the Democratic Republic of Georgia to carry out basic phage research and to use phage to treat bacterial infections in people. The Eliava Institute continues to this day to provide phage and treatments to thousands of patients from around the world. This period, circa 1915–1942, can be referred to as the classical period for phage therapy. During this time, phage were discovered, tested, and the beginning of their long-term development as antimicrobials, with the formation of companies around their distribution was underway. This would change quickly after the synthesis of penicillin in 1942.

The Silent Years (1943–2000): The Antibiotic Displacement and the Covet of the Curtain

On September 28, 1928, Alexander Fleming noticed the growth of *Staphylococcus* on a Petri dish was inhibited by what appeared to be a contaminating mold. Fourteen years would pass before the compound responsible for this inhibition, penicillin, was synthesized by Howard Florey and team and produced to scale to treat human patients. This remarkable discovery ushered in the era of antibiotic use, a golden age of medicine that largely continues to this day. The meteoritic rise of antibiotics all but eliminated the interest in the development of phage as clinically-used antibacterial agents, especially in the West. Major companies hitched their programs on the antibiotic train eventually yielding seven major classes of antibiotics encompassing greater than a hundred different compounds. Although largely discarded by the West as drugs, the rise in the biomedical research sector in the late 1940s in the United States and Europe fueled a strong interest in the use of phage as elegant model systems for the study of genetics, mutation, inheritability, and evolution. In fact, it was phage that were used to prove that DNA was the "transforming principle," a finding so revolutionary that many scientists adopted the use of phage in their laboratories. This work generated a wealth of information about the infectious and lysing properties of phage, and this knowledge helped to understand the limits and possibilities of phage therapy.

But in the East, phage therapy quietly pressed onward. The Eliava Institute in Tbilisi, Georgia continued to develop therapeutic phages, but perhaps because the knowledge and technology to make antibiotics was slower to spread to the East during the Cold War, phage therapy persisted in nearby countries that were a part of the Soviet bloc. In Poland, for example, the Hirsfeld Institute, which was formed in 1952, developed a strong record in the treatment of suppurative infections. To this day, Poland has an active program whereby patients can be evaluated to determine if they are good candidates for phage therapy, and, if so, can be treated

Phage Therapy Timeline

Fig. 2 A timeline for phage therapy. Phage therapy has progressed through three generalized eras characterized by discovery, quiescence, and revitalization. The current era, that of revitalization, is characterized by well-controlled studies in animal models of infection and an increase in the popular press reporting of some successful compassionate care cases in humans.

appropriately. Much of what we know of phage therapy in human patients comes from this period. There are numerous publications in either Russian or Polish journals. Most of the major themes discussed during the present time regarding phage therapy were to some degree also addressed during this period. This includes the use of oral phage to treat gastrointestinal infections, including shigellosis and salmonellosis. One study on this front, which occurred in the country of Georgia, stands out. More than 30,000 children were enrolled in a phage treatment trial to test the effect of a phage preparation directed against *Shigella*. Children on one side of the street were administered oral phage one time per week, while children on the other side were given the placebo. Weekly health checks were performed. The children that received phage were approximately three times less likely to demonstrate symptoms of dysentery.

Other phage preparations seemed to show efficacy in the treatment of localized or topical infections caused by *E. coli* or *Staphylococcus*, *Streptococcus*, and *Pseudomonas* spp. This included ulcers, surgical wounds, surface abscesses and other purulent infections. Yet other treatments focused on more invasive infections, including the lung, principally those caused by *Staphylococcus* and *Pseudomonas* spp. The comparison of phage therapy to antibiotic therapy was often performed, with phage in several cases apparently demonstrating superior efficacy; and, the combinatorial use of phage with antibiotics was reported to be more effective than antibiotics alone. Even human studies examining the production of neutralizing antibodies to phage was studied with overall a low incidence of neutralization reported. The language barrier, along with the fact that many trials and tests in these Eastern Bloc countries may not have been published, makes it difficult for the average Western scientist, let alone citizen, to critically evaluate the efficacy of phage therapy during this period. Nevertheless, there certainly is strong precedence for the use phage in treating human infections, an approach that continues to this day in this region.

The Resurgent Years (2000-Present): The Antibiotic Precipice and Renewed Hope

Within a year of the introduction of penicillin in 1942, bacterial strains resistant to the drug emerged. The generation of new antibiotics, along with entirely different structural classes of antibiotics distinct from penicillin in structure and mechanism of action, would continue to save countless lives. But as soon as a new class or version of antibiotics was heavily used, within a few years, resistance to that antibiotic would emerge. Resistance is now widespread, and new antibiotics to fill the gaps have not emerged at a pace sufficient to eliminate concern. Thus, in the last ~15 years or so, the conversation has once again shifted back to phage, a sort of second awakening for the idea of phage therapy. As a result, we are slowly learning more about the properties of phage as a dynamic treatment administered into a complex multiorgan being to treat bacterial infections, especially in the context of experimental animal models. With knowledge in this area expanding faster than ever, the well-controlled experiments that probably should (or would) have been done in d'Herelle's time are now just being formulated.

This third period in phage therapy is characterized by one important distinction: well-controlled studies in experimental models of infection. Efforts like this have generated a well-spring of useful information from everything from the breadth of possible bacterial infections treatable with phage to the parameters and variables that alter the experimental outcomes. These studies have addressed common nosocomial infections that have the potential to cause bacteremia, including the culprits *E. coli*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus*, as well as infections of the urinary, respiratory, and gastrointestinal tract. Major routes of administration and various doses have been tested, most with phage belonging to the genera Myoviridae, Podoviridae, and Siphoviridae. What is clear from these studies is that the intensity of investigation using controlled models is increasing, and, generally, phage are demonstrated to be effective at reducing bacterial burdens and improving the health of test subjects. A summary of some of the more comprehensive of these studies is shown in Table 1. This work, in combination with the medical community being at the precipice of the antibiotic resistance cliff, has led to even more adventurous attempts to use phage in the treatment of human infections in the West. In Europe, a large multinational clinical trial to assess the efficacy of phage killing *P. aeruginosa* on burn wounds (phagoburn) represents an important step in the West's acceptance of such an approach. The recent first-in-human systemic and successful administration of phages since the time of d'Herelle in the United States to clear an *Acinetobacter baumannii* infection, the so called Patterson case (*Antimicro. Agents Chemother.* Oct 2017), is also evidence of the growing willingness to move this technology forward. In this case, phage were administered to a male patient with systemic *A. baumannii* who was undergoing organ failure. The patient recovered quickly after phage treatment and is currently resuming a normal life. This case received much media attention and highlighted the utility of phage when all other approaches had been exhausted.

Dynamic Properties of Phage as an Adaptable Antimicrobial

Killing Activity Is Genetically Encoded

Perhaps the single greatest virtue pathogenic bacteria possess is mutability. Among a population of billions, it is theoretically possible that a single bacterial cell might acquire a mutation that confers a survival advantage against the backdrop of a strong selective pressure; this cell can then divide and become the founder of a new population, the progeny having inherited the beneficial trait. Take resistance to antibiotics as an example. It takes years to screen, identify, characterize, and test a new experimental compound in clinical trials, yet once introduced into the clinic or agriculture, resistant strains can emerge almost instantly. The power of this mutability emanates from four main mutation-acquiring strategies, and bacterial strains capable of all four reign supreme in overcoming medical measures designed against them. We can call this four-way intersection the mutagenic tetrasect, being comprised of conjugation (exchange of DNA between two bacterial cells via direct contact), transformation (uptake of

exogenous DNA, usually plasmids, from the environment), transduction (acquisition of DNA via infection with phage), and finally de novo mutation (substitution, excision, or insertion of DNA, usually by stochastic processes). Not all bacteria perform all these functions, some preferring one mechanism over another as an agent of change. But many pathogens of humans, including those that constitute our own microbiome, harbor a vibrant mutagenic tetrasect. With the ability to mutate so readily via these four mechanisms, and the drug-making progress taking years, one wonders how chemically fixed compounds can keep pace with evolution driven by the tetrasect.

At the heart of the killing ability of phage are protein elements that bind and lyse bacteria. Since their assembly is encoded by nucleic acid, they can change rapidly. This inherent changeability stands in contrast to all currently approved chemical antibiotics whose structure is fixed and cannot adapt to new conditions or bacterial strains. Phage are perhaps the only other biological entity on the planet whose replication can keep pace with, even exceed, that of bacteria. This prodigious reproduction levels the arms race. Not only are there more phage types than bacteria, meaning scientists have a nearly limitless supply of existing environmental phages to choose from, but they can also be evolved at an accelerated pace under controlled laboratory conditions. A 3 mL culture of growing bacterial hosts can generate up to 10^{11} phages. Spontaneous mutants can arise in every cycle. Although the vast majority of

Table 1 List of some relevant animal infection studies where phage therapy has been efficacious

Animal model	Phage (type)	Dose; route	Pathogen	Result	References
Gastrointestinal infection (in mice)	M13 (genetically engineered with <i>H. pylori</i> -specific MAbs)	10^7 PFU; Oral	<i>Helicobacter pylori</i>	When premixed with infectious agent prevented bacterial growth in stomach	Cao et al. (2000)
Septicemia (in mice)	CK2, 153A-5, and 153A-7	10^8 PFU; I.V.	<i>Vibrio vulnificus</i>	Reduced disease, edema, and bacterial CFU in lesions and liver	Cerveny et al. (2002)
Bacteremia (in mice)	ENB-6	10^4 – 10^9 PFU; I.P.	<i>Enterococcus faecium</i>	With high dose, 100% survival	Biswas et al. (2002)
Wound infection (in rabbits)	LS2a	10^5 – 10^9 PFU; S.C.	<i>Staphylococcus aureus</i>	Lower bacterial CFU at infection site and abscess reduction	Wills et al. (2005)
Gastrointestinal infection (in broiler chickens)	NCTC 12669 and 12,671 (<i>Myoviridae</i>)	10^9 – 10^{10} PFU; Oral	<i>Campylobacter jejuni</i>	Reduction in caecal colonization (1–3 log)	Wagenaar et al. (2005)
Gastrointestinal infection (in mice)	SP15, 21 and 22	10^8 – 10^{10} PFU; Oral	<i>Escherichia coli</i> 0157:H7	With daily administration, reduction in <i>E. coli</i> in feces and gastrointestinal tract	Tanji et al. (2005)
Septicemia (in mice)	KPP10 (<i>Myoviridae</i>)	10^{10} PFU; Oral and I.P.	<i>Pseudomonas aeruginosa</i>	Increased survival rate with both routes of treatment	Watanabe et al. (2007)
Pulmonary infection (in mice)	BcepIL02	10^9 – 10^{10} PFU; I.N. and I.P.	<i>Burkholderia cenocepacia</i>	Reduction in bacterial density in lungs with I.P. route	Carmody et al. (2010)
Bacteremia (in mice)	A1122	10^9 PFU; I.P.	<i>Yersinia pestis</i>	Increased survival rate	Filippov et al. (2012)
Typhoid fever (in mice and chickens)	UAB_Phi20, 78 (<i>Podoviridae</i>) and Phi87 (<i>Myoviridae</i>)	10^{11} PFU; Oral	<i>Salmonella typhimurium</i>	Increased survival rate	Bardina et al. (2012)
Ulcers (in mice)	D29	10^8 PFU; S.C.	<i>Mycobacterium ulcerans</i>	Reduction in swelling, ulceration and bacterial burden	Trigo et al. (2013)
Gastrointestinal infection (in rabbits)	ATCC 51352-BI, B2, B3, B4 and B5	10^8 PFU; Oral	<i>Vibrio cholerae</i>	Reduction in fecal bacterial CFU and severity of diarrhea	Jaiswal et al. (2013)
Septicemia (in mice)	S13'	10^{10} PFU; I.P.	<i>Staphylococcus aureus</i>	Increased survival rate	Takemura-Uchiyama et al. (2014)
Pulmonary infection (in mice)	K56–2 and C6433	Up to 10^{11} PFU; aerosolized	<i>Burkholderia cepacia</i>	Reduction in bacterial load in lungs	Semler et al. (2014)
Pneumonia (in mice)	Phi1513 (<i>Siphoviridae</i>)	10^7 to 10^9 PFU; I.N.	<i>Klebsiella pneumonia</i>	Increased survival rate, decreased weight loss and reduction in bacterial burden	Cao et al. (2015)
Gastrointestinal colonization (in mice)	AL505_P1, P2, P3 (<i>Siphoviridae</i> , <i>Myoviridae</i> and <i>Podoviridae</i>)	10^5 to 10^7 PFU; Oral	<i>Escherichia coli</i> UPEC	Reduction in intestinal colonization	Galtier et al. (2016)
Gut-derived Bacteremia (in mice)	HP3 (<i>Myoviridae</i>)	10^9 PFU; I.P.	<i>Escherichia coli</i> ExPEC	Reduction in bacterial load in organs and disease	Green et al. (2017)
Pulmonary infection (in mice)	PAK_P1 (<i>Myoviridae</i>)	10^8 PFU; I.N.	<i>Pseudomonas aeruginosa</i>	Increased survival rate	Roach et al. (2017)

I.V. = Intravenous; I.P. = Intraperitoneal; S.C. = subcutaneous; I.N. = intranasal.

these mutants may not acquire new binding or lytic activity (in fact, most mutations are likely to be detrimental to the fitness of the phage), some novel mutations may enhance infectious ability. These mutations fall into three classes; (i) those that enhance binding to the bacterium, perhaps via mutation of the tail fibers, (ii) those that enhance postbinding infection (including adsorption, injection, production of phage proteins, replication and packaging), and (iii) those that enhance lysis. Designing clever ways to generate and select for mutations that enhance these properties could, conceivably, produce a more efficacious antimicrobial, and on the order of hours to days. There is no drug-making pipeline that exists today with such versatility.

Feasibility and Cost Are Low

One advantage phage may possess as an antimicrobial is the low technical know-how needed to find a phage that kills any given strain of bacteria, and at relatively low cost. In 2014, the estimated cost to bring a new drug to market was greater than 2 billion dollars and required approximately 10 years of development. This is simply too costly and too long for new chemical antibiotics to be developed to combat the emergence of drug-resistant strains, which may arise in the clinical population on the order of weeks to months. Should a drug-resistant strain of bacteria arise in a hospital or health-care clinic, the diversity and evolvability of phage allows for an active phage to be isolated against that strain on a relatively short time scale. Several laboratories have demonstrated that phage can be isolated from the environment or evolved in real-time that are effective at killing pathogenic bacteria (even circulating pandemic strains) on the order of days or weeks. The cost in developing these phage preparations is in the hundreds to thousands of dollar range and, if production was streamlined, could even be lower. The technical knowledge to isolate, purify, and test most phage is low, and for the most part does not require expensive/complicated instrumentation. One might envision that a standardized pipeline of phage discovery, characterization, testing, and scalable production could be created that responds to each new drug-resistant threat as it emerges, either at the level of a company or local health-care institution.

Phage Cocktails and Adjuvants Can Overcome Resistance

The mechanism by which phage kill bacteria are distinct from the mechanism by which chemical antibiotics work. This means that resistance against antibiotics is unlikely to confer a selective advantage when faced with phage. Because of this, phage should have no barriers toward efficiently killing multidrug resistant bacteria. It does not, however, mean that bacteria will not develop resistance to phage. Bacteria and phage have been coevolving for quite possibly billions or more years. Phage resistance is common and well documented, even during the course of a single culture experiment or animal infection. The advantage of phage, unlike rigid chemical antibiotics, is that although resistance will be frequent, finding or adapting a counter phage to kill the phage-resistant strain can be readily achieved. Each phage may kill by a slightly different mechanism, or use different surface receptors for binding. It would be difficult for bacteria to overcome all the ways a phage can infect. There are also reports of bacteria becoming less fit and more easily killed by the immune system after they become resistant to phage. Indeed phage often use important surface proteins as receptors. Mutation or loss of these receptors may prevent a phage from binding, but it may come at a fitness cost to the bacterium.

There is also well documented evidence, in both humans and animal models, that phage used in combination with antibiotics is more effective than either alone. Since both use a different mechanism to kill, the likelihood of developing resistance simultaneously against both activities is lower than for each individually. Even more so, a cocktail of many unique phage, especially if they use different mechanisms to infect, will be very difficult to evolve resistance to on an appreciable timescale. A cocktail of phages plus an antibiotic might even be more effective. Since many physicians may be reluctant to exclude antibiotics from any treatment, the combinatorial use of phage and antibiotics may be a more favorable option for future phage therapy. In this case, phage may be considered a sort of “green” adjuvant to antibiotic action, a safe and environmentally friendly alternative that enhances the effectiveness of antibiotics. These phage adjuvants may also lower the effective dose of antibiotics, thereby decreasing the levels of resistance. Such a property may also bring previously unusable antibiotics back into the fold.

Targeted and “Self-Dosing”

One of the potential benefits of phage is that they are highly specific to the bacterium they infect. This means they will have low off-target effects since they do not infect eukaryotic cells. A major problem with antibiotics is that their nonspecific broad spectrum activity can also kill beneficial microbes that inhabit our gastrointestinal tract. Of course, the broad spectrum property is an advantage when a clinician does not yet know the species of bacterium that is infecting a patient; a sweeping approach is likely to be more successful. But clearing out protective species in the gut, which eliminates “colonization resistance” and allows pathogenic species to occupy previously occupied niches, can lead to serious infections. A classic example of this is the emergence of *Clostridium difficile* infections in the nosocomial setting. Phage are so selective that not only can they target a species of bacterium, they can also be strain-specific. Where knowledge of the type of bacterium that is infecting the patient is known, the use of phage would spare intestinal commensals while killing only the bacterial pathogen. Such an approach might reduce the incidence of nosocomial infections that are associated with wiping out the native intestinal flora. Of course, rapid diagnosis and typing of the infection is needed beforehand unless a broadly-acting cocktail is used that can target the most likely pathogens present during the infection.

Another virtue of phage is that they may be a “self-dosing” drug that will release new infectious particles proportional to the density of the target bacterial host. This property has the virtue of amplifying the drug at the precise location where the bacteria are, thus concentrating the drug in a higher density at the site of infection that might otherwise not be achievable by any other delivery

method. Furthermore, once the target bacterial cells are killed, their density will decrease, and so will the concentration of phage. Should resistant cells arise at this point, it is possible mutant phage, having arisen on the spot, may re-infect, thereby further amplifying the response. Such activity may keep the bacterial population at a low density so that the immune system can adequately clear any remaining cells.

Guidelines for Phage Therapy

For all the realized and potential virtues of phage therapy, there are also substantial obstacles, each of which will need to be addressed if this approach is to gain wide-spread acceptance in the lay and medical community.

Safety

Phage are “generally regarded as safe” by the US Food and Drug Administration with at least one phage product approved for use to clear *Listeria* species from poultry. As discussed above, only compassionate care use of phage has been approved for human use in the US, largely through the Investigational New Drug (IND) process. Empirical evidence in animal models and the administration of phage to humans (mostly in the East, but cases in the West confirm) that even very high doses of purified phage do not yield adverse reactions. Working groups under the European Medicines Agency has formulated some useful guidelines pertaining to safety, and numerous academic researchers have written extensively about them. A comprehensive attempt to summarize these points is discussed below.

It is good practice to sequence any phages for human use. Whereas there is not a strong consensus about the type of genes a phage should possess before it can be used therapeutically, there is consensus on what genes it should not contain. A phage should not encode any elements that may confer resistance to antibiotics, known or suspected virulence factors (including protein toxins, adhesins, secretion systems, and nutrient transporters), and/or elements that promote the integration of phage DNA into bacterial or human cells. This implies that the phage will be free of lysogenic elements.

It would be helpful if there were some preclinical data available, perhaps from animal models, on the type of immune response the phage may produce. Commercially available assays can easily assess the complete cytokine response from a small sample of blood, and animal temperature can be readily measured with time. For long-term use of phage (>2 weeks), the production of neutralizing antibodies can be determined using assays already reported in the literature. Of course, these considerations are only applicable to phage that will enter systemic circulation. Phage used topically may be less restricted in adherence to these considerations.

Finally, currently phage can only be produced in a bacterial host. This means that products that might normally be toxic or induce inflammation in a human have the potential to contaminate the phage preparation. There are several density-dependent and organic-solvent based methods to remove these bacterial products, and they should be considered when readying phages for use. Post purification testing should include some knowledge about the endotoxin levels (lipopolysaccharide—can be measured by commercially available assays), exotoxin (if the bacterial host used to grow the phage is a pathogen—pyrogen tests in animals), and buffer and/or cryoprotectants used to purify or store the phage. It goes without saying that the preparation should be sterile.

Storage

Each phage preparation will require some standardization of its storage capacity, including temperature, buffer conditions, and how much potency loss is acceptable before new preparations need to be made. Considering that phage come from the environment and are thus exposed to extreme conditions, they may have the advantage of not requiring refrigeration or complex preserving formulations for their storage. Regardless of the conditions that are chosen, the half-life of the preparation will need to be determined, both during storage and once the seal is broken immediately prior to therapeutic use. This also implies that the bacterial test strain also be standardized so that loss of viability can be ruled out as a complicating factor in phage testing.

Phage Banks and Process Strategies

There currently is no formal or structured system in the West for phage therapy from diagnosis to treatment. There are several ways one may structure a phage treatment system, none of which are mutually exclusive. The first is the conventional way drugs are currently made, sold, and used. A company identifies an efficacious phage preparation, attains the intellectual property around this preparation, performs the quality control under good manufacturing practices, and sells based on need. The ever changing ability of phage make the acquisition of intellectual property and patentability surrounding phage use difficult. In addition, the streamlined production of antibiotics has a 75 plus year head-start. These obstacles make taking the plunge into the development of phage perceived as not economical. The current use of phage in people is very personalized. For investment in this area to be considered by the private sector, a more standardized application may be necessary.

The second approach is to generate a national repository of therapeutic phages that would be managed by subsidiary government organizations or subcontractors. There is precedence for this since several vaccines against uncommon but nonetheless serious infectious diseases are maintained in a type of national stockpile should their use be suddenly necessary. This approach

would require continuous investment of public resources for their maintenance, possibly offset in costs via their purchase when needed.

A third approach entails the development of individual phage treatment centers at medical institutions, be it hospitals, clinics, or allied academic and research units (such as medical schools). There may be a strong incentive for this model due to the overburdening liability associated with nosocomial infections. In addition to being deadly, bacterial sepsis and/or chronic bacterial infection is one of the most expensive in-patient diseases and a sizable fraction of these originate in the hospital while the patient is being treated for another ailment. There are well-documented instances of hospitals or clinics having high carriage of a particular multidrug resistant strain. It may even be localized to a ward or unit of an institution. Phage can be viewed as a type of intra-institutional infectious disease control mechanism. A bank of phages can be developed and maintained that is highly specific to the bacterial pathogens common to that institution. Upon plating or culture growth of the pathogen in question, hundreds to thousands of different phage preparations can be easily tested for lytic activity using automated methods, those phage pulled, quickly assembled into a cocktail, and subsequently administered to the infected patient. In addition to potentially being an in-house, low-cost solution to a much larger problem, the use of phage in this capacity may reduce the antibiotic use, encouraging good stewardship and decreasing resistance. Should resistance arise, one can go back to the original phage collection and make a new cocktail from either phage isolated from the environment or via their controlled evolution in the laboratory. An overview of these processes is shown in Fig. 3.

Treatment and Pharmacology

In people and in animal models of infection, phage have been applied topically, orally, rectally, subcutaneously, intraperitoneally, intramuscularly, and intravenously. In general, very few adverse reactions have been noted. Much like antibiotics, it seems sensible to apply the delivery method that is most likely to reach the intended bacterial target. Topical application might be useful for infections of the skin (example, diabetic foot ulcer) or wound dressings (burn victims) and may be less hindered by fears of delivering a virus systemically. Should harmful pathobionts be “edited” from their reservoir in the gastrointestinal microbiome, oral application of phage protected from the low pH of the stomach may be of value. The oral prophylactic use of phage to protect against diarrhea-causing bacteria (for example for travelers or children in unsanitary parts of the world) may also be useful. Clearly, systemic infections will need systemic delivery of phage.

Very little is understood about the half-life of different types of phages delivered via various routes. The relationship between phage size (which may affect its distribution and penetrance) and surface protein content (which may affect its ability to interact nonspecifically with host tissues or specifically with the host immune system). Long-lasting circulating phages have been identified by serially passaging phage in murine hosts, but the biological properties of phage that confer this longevity are still unexplored. The host factors that have the greatest impact on the efficacy of phage are also a rich ground for further research. Numerous reports clearly support a role for the host’s immune system (either macrophages or antibody) in altering phage activity, but the effects of temperature, blood components including small molecules (salts, sugars, metals, etc.), xenobiotics (other drugs, ingested foods), and cells/complement etc., are not worked out. For example, some of the earliest phage literature invoked a significant role for some divalent metals (especially calcium and magnesium) in phage activity in culture, but the role of these factors during systemic action is unscrutinized. Phage may circulate to major organs and even can enter the central nervous system. They accumulate in the spleen and are readily excreted. But the long-term effects of phage on the human health, especially the immune response, will also need to

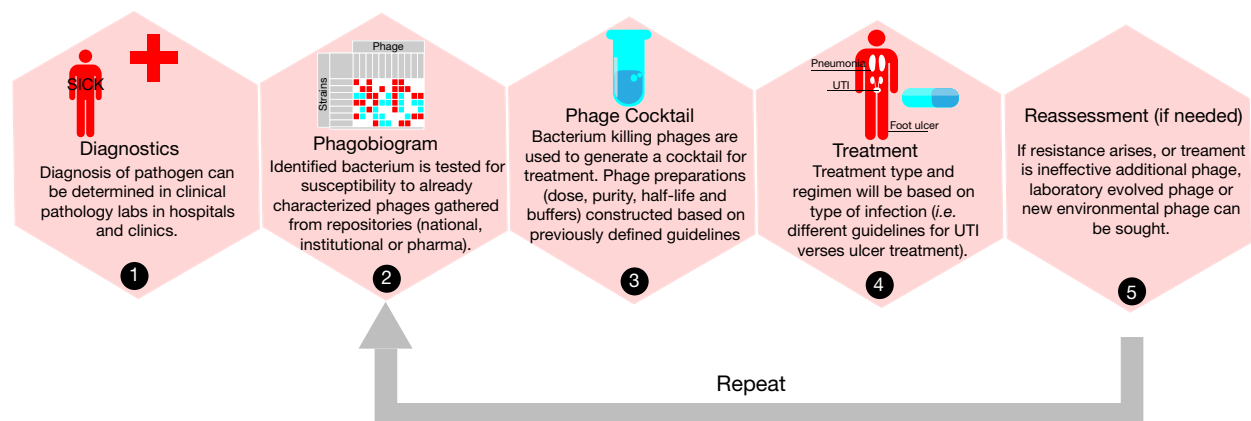

Fig. 3 A pipeline primer for the use of phage to treat human infections. Following the diagnosis and identification of the infecting bacterium, a single or a cocktail of phage are generated from a stored phage repository that are highly active against the target pathogen. Phage are propagated and administered according to defined criteria for that particular clinical infection and progress monitored. Should treatment not be effective or resistance emerge, a new series of phage are identified from the repository, or identified from the environment, or experimentally evolved in culture, and re-applied.

also be studied. To be fair, these questions also remain for many approved and commonly used drugs, but it certainly is clear that the pharmacology of phage after their administration is a giant black box waiting to be illuminated.

Engineered Phage or Phage Products

Advances in molecular biology, cloning, and technology have also facilitated the generation of phage preparations with enhanced features. The sequencing of phage genomes has allowed for the identification of closely related phages that differ in target specificity. Swapping the tail fiber genes of these related phages leads to lytic activity that is dependent on the specificity of the tail fiber, thereby demonstrating that the host range of phage can be either expanded or narrowed dependent on the constitution of their binding elements. Using this knowledge, others have generated phage engineering platforms, often using heterologous hosts such as yeast, as a synthetic system to generate phage with controlled targeting specificity. One might envision the day when an entire phage genome is constructed from a computer template, differing only in the elements that enhance activity or specificity, the nucleic acid synthesized, and phage produced in a host that lacks toxic elements.

There are numerous reports, and even some start-up biotechnology companies, centered around the use of phage products as antimicrobials. The hallmark feature of these include the use of phage lysins and/or holicins, as phage-independent bacterial killing proteins. After infection, phage often make a holicin to cleave the inner membrane so that a specific lysin can attack the intervening peptidoglycan. The cell then bursts, no longer able to withstand the osmotic pressure. Lysins contain numerous advantages over phage. These include that they; (i) are a protein and thus will not change during preparation or treatment, (ii) they are highly active at relatively low concentrations, (iii) are recombinant and thus can be enhanced or built with new modules simply by adding, removing, or mutating the gene that encodes them, and (iv) have demonstrated activity in several models of infection, including a *S. aureus* endocarditis model. Concerns with lysins include that the host may produce neutralizing antibodies (although evidence seems to suggest it does not occur frequently) and that they do induce an increase in several inflammatory cytokines (although the ramifications of this are not yet worked out).

Finally, the possibility of using noninfectious, nucleic-acid free phage, termed phagocins, has been raised. Phagocins appear to efficiently kill bacteria without lysis, which may reduce the release of endotoxin, and are stable because they lack any ability to mutate. The more defined and controlled nature of phagocins also means they might be more amenable to intellectual property claims. Future work will be needed to determine the level of efficacy and safety phagocins offer over phage or their lysins.

Development of Industry

One sign that phage therapy may have life is that companies have sprouted around the commercial use of phage. This includes PhagoBioderm, a biodegradable polymeric film that contains bacteriophages with demonstrated efficacy against ulcers that are typically resistant to antibiotic treatment. In the US, a company called Intralytix is undertaking phase I clinical trials for diabetic foot ulcers. A Portugal biotech company (Technophage) received approval in 2014 for a phase I trial using TP-201, a cocktail of bacteriophages for the treatment of chronic ulcers. Pherecydes Pharma, a France based company, has a product called Pneumophage in its pipeline that stands at the preclinical stage. This product is intended for the acute respiratory treatment of *P. aeruginosa*. A US based company (EnBiotix) developed an engineered phage EBX-003 in 2016 to treat prosthetic joint infection through the expression of a biofilm degrading enzyme.

Known Mechanisms of Phage Resistance

Bacteria may become resistant to phage in several ways (Fig. 4). One such mechanism includes the modification of cell surface receptors. This includes mutation or a variation in expression. Another mechanism of resistance to phage includes the digestion of phage nucleic acid via the production of endonucleases, including targeting nonmethylated foreign DNA. Finally, CRISPR Cas systems acquire phage DNA from previous infections and transcribe these elements into small interfering RNAs that guide nucleases the phage DNA.

Future Hurdles

Bacteria evolve at a pace that is greater than our ability to make new antibiotics. Phage are a promising option to turn the evolutionary table back on pathogenic bacteria since the adaptability of phage is just as great if not greater. Despite this potential and demonstrated efficacy in humans and animal models, three main challenges remain.

First, we must change our culture. Either we change the way we develop and approve new drugs, or we develop and approve new drugs that change. Whereas the first option is unlikely to occur for chemically-derived new drugs, the second will require an unconventional approval process. Entities that can change in real-time, which can be a great advantage in some cases, must be given some leeway to do so. It is not just phage that would benefit from a different set of guidelines, CRISPR-based gene editing, gene therapy, and T cell treatments of cancer or viral infections also would fall under this umbrella. Like phage developed against a particular strain of bacteria in a certain clinical context, each of these approaches is specific for the problem (and sometimes patient), at hand. Basic parameters will need to be met (some discussed above are acceptable endotoxin levels, knowledge of

Fig. 4 Resistance to phage. Bacteria can acquire resistance to phage in a number of ways, including de novo mutation of receptors or other proteins needed for binding or nucleic acid injection, the digestion of phage nucleic acid, or via the use of CRISPR immunity systems.

neutralization, half-life, shelf-life, etc.), but these parameters will need universal consensus for each particular type of infection. Blanketing all phage therapy under one set of guidelines will not work, and there must be some way the process can be made profitable to encourage development and investment. This makes revising intellectual property guidelines an important part of the process. If not, there will need to be a basic understanding in our society that government dollars will be spent to maintain phage banks and pipelines for use by clinics in need.

Second, we must accelerate basic and clinical research into phage therapy. This includes determining the type of phages to study, the molecular mechanisms by which they kill and by which bacteria become resistant, their pharmacokinetic and storage properties (phagacology), the host factors that may affect efficacy, their short and long-term safety, and the leveraging of technology to genetically enhance these properties, either via whole virus or through the use of phage lysins or phagocins. Animal models that allow researchers to assess these properties should be agreed upon and standardized, preferably with results that translate to the human condition, and carefully controlled clinical studies in humans initiated. Funding for this work should be a priority for grant-issuing institutions and the public educated on the pros and cons of the approaches and research.

Finally, there must be investment, both in industry and the academic or private hospital system, in the infrastructure, expertise, and personnel needed to execute phage therapy as an accepted medical practice. Initial considerations were presented above but loosely include the support of phage banks, the rapid and automated ability to screen these banks for efficacious phage to pack into cocktails, and the wherewithal and confidence to administer clean and safe preparations for the infection at hand. Much like hospitals have invested in Diagnostic Microbiology labs to culture, type, and test the sensitivity to antibiotics in-house, so too should there be a similar commitment to the generation of a real-time drug capable of efficient clearance of multidrug resistant pathogenic bacteria.

CLP	common lymphoid progenitor
CMP	common myeloid progenitor
DC	dendritic cell
EAR	eosinophil-associated RNases
EPO	eosinophil peroxidase
GMPs	granulocyte/monocyte progenitors
HSCs	hematopoietic stem cells
MBP	major basic protein
MDP	macrophage and DC progenitor cell
MEPs	megakaryocyte/erythrocyte progenitors
moDC	monocyte-derived DC
MPO	myeloperoxidase
MPS	mononuclear phagocyte system
NET	neutrophil extracellular trap
NK	natural killer
pDC	plasmacytoid DC
PICD	phagocytosis-induced cell death
PMN	polymorphonuclear neutrophil
PRR	pattern recognition receptor
RBCs	red blood cells
ROS	reactive oxygen species
SOD	superoxide dismutase

Introduction

Phagocytes and phagocytosis were first described by Elie Metchnikoff in the late 1800s. He identified two groups of phagocytic cells during his studies of bacterial infection and named these cells macrophages and microphages. These cells could be differentiated further by staining methods developed by Paul Ehrlich and colleagues. Metchnikoff reported that the cells he named “microphages” were the same leukocytes Ehrlich described as polynuclear cells (later “cells with polymorphous nuclei”). These microphages are now known as granulocytes or polymorphonuclear leukocytes. Metchnikoff reported the ability of phagocytes to ingest invading microbes and thereby contribute to natural or innate immunity. Our understanding of phagocyte biology, including development, function, and turnover, has increased significantly since the early work by Metchnikoff and Ehrlich. Many of the most recent discoveries, especially those related to the origins and development of phagocytes, have been made possible by advances in technology and improved methodology. Inasmuch as information and detailed knowledge related to phagocyte biology is extensive, this article is not intended to provide a comprehensive discourse on phagocytes and/or phagocyte biology. Rather, it provides an overview of selected areas of phagocyte biology that can serve as a starting point for the interested reader.

Phagocyte Development

Hematopoiesis

Hematopoiesis is the formation and development of blood cells. A process named primitive hematopoiesis, which produces red blood cells (RBCs) and macrophages, occurs in the yolk sac early during embryogenesis. As embryos mature, hematopoietic stem cells (HSCs) are formed. All subsequent blood cells are derived from HSCs. This type of hematopoiesis is termed definitive hematopoiesis. Our understanding of this process, which includes development of phagocytic cells, such as granulocytes and

monocytes, has changed in recent years. According to the traditional model of hematopoiesis, the initial differentiation of pluripotent hematopoietic stem cells (HSCs) leads to two distinct progenitor stem cells – a common myeloid progenitor (CMP) and a common lymphoid progenitor (CLP). CMPs differentiate further into granulocyte/monocyte progenitors (GMPs) and megakaryocyte/erythrocyte progenitors (MEPs), which in turn become mature myeloid cells (granulocytes and mononuclear phagocytes) and platelets or RBCs. CLPs differentiate into B cells, T cells, and natural killer (NK) cells. A key tenet of the traditional model is the stepwise maturation of bone marrow progenitor and precursor cells into specific types of leukocytes. However, recent studies have revised our understanding of hematopoiesis into a more dynamic model. For example, it is now known that HSCs are a heterogeneous population of cells from a functional standpoint, and differentiation to mature blood cells occurs over a continuum rather than *via* distinct maturation steps, as per the traditional model of hematopoiesis. In any case, the development of each type of phagocyte is discussed in more detail below.

Granulocytes

Human granulocytes are a subset of myeloid cells that in circulation are comprised of <1% basophils, 2%–5% eosinophils, and ≥95% neutrophils. Collectively, these cells are also known as polymorphonuclear leukocytes (Fig. 1). A fourth cell type, known as a mast cell, is functionally similar to a basophil (and is derived from a common basophil/mast cell precursor) but is a tissue-resident cell with a longer life-span by comparison. Mast cells, like basophils, contain effector proteins stored within cytoplasmic granules. Although the term “granulocyte” has been used historically for basophils, eosinophils, and neutrophils (cells in the bloodstream), an argument could readily be made to classify mast cells as granulocytes. Granulocytes and granulocyte precursors constitute ~60% of all cells in bone marrow; 50%–70% of white cells in circulation are granulocytes. Thus, there is enormous production and turnover of granulocytes in humans – approximately 10^{11} granulocytes per day in a healthy human adult.

Neutrophils

Neutrophils, also known as polymorphonuclear neutrophils (PMNs), are the most prominent cellular component of the innate immune system. Their primary function is to ingest and kill invading bacteria and fungi. Neutrophils are terminally-differentiated cells and thus have a relatively short lifespan, which explains in part the need for high steady-state production of these cells, as mentioned above. In healthy adults, neutrophils develop in bone marrow for 5–6 days (excluding the time needed for differentiation of mitotic precursor cells) and are then released into the bloodstream. Neutrophils circulate in the bloodstream for ≤1 day, during which time they function as first-responder cells and can be recruited rapidly to sites of injury and/or infection. Neutrophils that are not recruited to the tissues by an inflammatory signal ultimately re-enter tissues and undergo apoptosis spontaneously (discussed below). The total lifespan of neutrophils is ~9–10 days.

PMNs are readily identified by a characteristic multi-lobed nucleus and cytoplasmic granules (hence the term granulocyte) (Fig. 1). Key components of neutrophil microbicidal activity are contained within cytoplasmic granules (see below). There are at least three types of granules: azurophilic granules, specific granules, and gelatinase-containing granules. A fourth cytoplasmic organelle, the secretory vesicle, contains an array of membrane-bound receptors that can be readily mobilized to enrich the plasma membrane with cell surface receptors. These granule subsets form sequentially during neutrophil production (granulopoiesis) in bone marrow. The azurophilic granules, named originally because of their ability to be stained readily with the dye azure A, form at the promyelocyte stage of neutrophil development. Inasmuch as azurophilic granules are the first to form during granulopoiesis, they are also known as primary granules. The primary granules are the sole repository for myeloperoxidase (MPO) and are therefore peroxidase-positive granules. Specific granules form next (and are also known as secondary granules), followed by gelatinase-containing granules and secretory vesicles. These granules and vesicles lack MPO and can be classified as peroxidase-negative granules. Each type of granule subset contains a specific set of proteins in the membrane or lumen that is targeted to that organelle based upon timing of protein synthesis. Thus, neutrophil granule contents reflect the proteins being synthesized at that point during granulopoiesis.

Fig. 1 Human granulocytes. Human blood cells were stained with a modified Wright-Giemsa stain and visualized on a light microscope at 100× magnification.

As neutrophils mature, the capacity for gene expression and protein synthesis decreases. Thus, microbicidal proteins and enzymes required to ingest and kill microbes need to be preformed and stored in granules and secretory vesicles, and mature neutrophils are fully equipped to carry out their role as frontline innate host defense cells. It is noteworthy that the stores of microbicidal components are not resynthesized, and new granules do not form in mature cells – a characteristic consistent with a terminally differentiated cell that has a short lifespan. That said, circulating neutrophils retain some capacity for gene expression and protein synthesis, which is needed to maintain functional capacity for extended periods (hours) and facilitate apoptosis and turnover.

Basophils, eosinophils, and mast cells

Basophils, eosinophils, and mast cells are widely known for their prominent roles in allergic responses. Basophils and eosinophils mature in bone marrow as granulocyte precursors and are then released into circulation as mature cells. By comparison, mast cell precursors are released into the bloodstream and ultimately migrate to tissues, where they differentiate into mature and fully functional cells.

Basophils and eosinophils are polymorphonuclear leukocytes that can be readily identified by distinct morphology on a microscope slide preparation, as described by Ehrlich. Indeed, granulocytes were named by their characteristic staining patterns with basic aniline dyes (basophils), acid aniline dyes such as eosin (eosinophils), or neutral dyes (neutrophils). Following stain with a modified Wright-Giemsa stain, basophils can be identified by their large cytoplasmic granules that stain dark purple, whereas eosinophils have a bilobed nuclei and large cytoplasmic granules that stain orange/red (Fig. 1). The granules of basophils and eosinophils are unique to each of these cell types and contain proteins that are key to their respective roles in immune and inflammatory responses (see below).

Eosinophils, like basophils, regulate immune and inflammatory responses by secreting effector proteins stored within cytoplasmic granules (see below). These secreted proteins contribute to the prominent role played by eosinophils in the response to allergens and in host defense against microorganisms, including parasites, viruses and bacteria. This antimicrobial activity is largely extracellular, although these cells can phagocytose bacteria to a limited extent (compared with neutrophils). In addition, eosinophils have the capacity to secrete a host of cytokines and chemokines, and they function as antigen-presenting cells. Eosinophils remain in circulation for ~1 day and then migrate into tissues.

Recent evidence suggests mast cells are derived from a common basophil/mast cell progenitor and thus share many functional similarities with basophils, such as a prominent role in allergic inflammation. Whereas basophils circulate as mature cells in the bloodstream, mature mast cells reside almost exclusively in tissues. Thus, only mast cell precursors are found in circulation. It is also notable that mast cells have a long lifespan (weeks or months) compared to other granulocytes such as basophils (a few days). Mast cells are relatively abundant in skin and mucosal tissues, areas that are often exposed to invading microorganisms. As such, they are ideally positioned to coordinate innate and adaptive immunity, which is achieved by secretion of cytokines, chemokines, and effector proteins stored within mast cell granules. During activation, mast cells release numerous inflammatory mediators, including histamine (major contributor to allergic inflammation) and chemokines that recruit neutrophils.

Although basophils, eosinophils, and mast cells are myeloid cells, and eosinophils and mast cells can phagocytose bacteria, these cells are perhaps more widely considered as immune regulatory cells rather than phagocytes. Therefore, our discussion of the role of these cells in innate immunity is brief, and we refer the interested reader to review articles listed in the Further Reading section (*e.g.*, Travers and Rothenberg, 2015; Rosenberg *et al.*, 2013).

Mononuclear Phagocytes

Monocytes, macrophages, and dendritic cells (DCs) comprise a group of cells known as mononuclear phagocytes. These phagocytic leukocytes are important for innate immunity and can interact directly with invading microorganisms. In addition, they coordinate the acquired immune response, in part by producing chemokines and cytokines, and by functioning as antigen presenting cells. Therefore, these cells serve as a key bridge between innate and acquired immunity. Lastly, these cells contribute significantly to tissue and immune system homeostasis, largely by removing dead and dying host cells.

Our understanding of mononuclear phagocytes has evolved considerably since they were first described by Metchnikoff. It was Metchnikoff who first proposed a macrophage system, which was superseded by Ludwig Aschoff's reticuloendothelial system and then the mononuclear phagocyte system (MPS), as described by Ralph van Furth and colleagues. According to the original MPS, monocytes develop in bone marrow from mitotic precursor cells known as promonocytes, which in turn differentiate into all mononuclear phagocyte subsets. Based on this model, mature monocytes are released into circulation as terminally-differentiated end cells, which then enter tissues and differentiate to macrophages. Many of the basic tenets of the MPS remain today. For example, human monocytes can be differentiated into macrophages and specific dendritic cell (DC) subsets *in vitro*, a finding that supports the canonical MPS. However, the extent to which this occurs *in vivo*, especially during inflammatory states, remains incompletely determined. Studies in mice identified a common macrophage and DC progenitor cell (MDP) in bone marrow. These MDPs can develop into monocytes, macrophages, and dendritic cells *in vivo*, which is also largely consistent with the MPS theme. On the other hand, recent studies indicate that many of the long-lived (and self-renewing) tissue-resident phagocytes present in adults, including macrophages, dendritic cells, and Langerhans cells, arise from prenatal progenitor cells in the yolk sac or fetal liver during embryogenesis, and are thus not derived from monocyte precursors in bone marrow. That is, these tissue phagocytes are established before birth and maintained through adulthood. Although there have been many important discoveries in the area of mononuclear phagocyte development, this latter finding is arguably one of the most notable changes to the canonical MPS.

Monocytes

Human peripheral blood monocytes are typically identified and classified by the presence of a bean-shaped nucleus and the levels of specific surface receptors, such as CD14, CD16, CD11b, and CX3CR1 (fractalkine receptor). Mature monocytes comprise 5%–10% of the leukocytes in human blood ($\sim 2 \times 10^5$ cells/mL) and are in circulation for 1–2 days before migrating into tissues. Inasmuch as monocytes play a key role in the acute inflammatory response and innate immunity, they can be recruited readily from the bloodstream to sites of inflammation by multiple host or microbe-derived molecules. Monocytes in tissues function as phagocytic cells of the innate immune response, and much like neutrophils, ingest and kill invading microorganisms (see below). It is noteworthy that as tissue monocytes differentiate further into macrophages or DCs, they lose MPO-containing granules (lysosomes). Whether monocytes ultimately differentiate into specific macrophage or DC subsets is likely dictated by molecules present during the inflammatory response. Monocyte-derived tissue macrophages have significant biosynthetic capacity and can live for weeks to months in tissues.

Macrophages and DCs

Macrophages are phagocytes located in tissues throughout the body. These cells represent an integral component of innate and acquired immunity, and they contribute to tissue homeostasis. Macrophages established from yolk sac progenitors during embryogenesis (during primitive hematopoiesis) have the capacity to self-renew and are maintained independent of myeloid precursor cells in bone marrow. These macrophages include Kupffer cells of the liver, Langerhans cells in skin, and microglia in the brain. However, macrophages in some tissues (*e.g.*, skin, heart, and gut) are maintained by bone marrow precursor cells and are derived from monocytes. During specific conditions, such as inflammation and/or infection, there is a significant (and transient) increase in monocyte-derived macrophages. From a functional standpoint, macrophages have been traditionally categorized as belonging to M1 (classic) or M2 (alternative) phenotypes. An approximation of the level or type of macrophage activation is known as macrophage polarization. M1 macrophages are proinflammatory cells, whereas M2 macrophages are immunosuppressive and contribute to tissue repair and wound healing, although it is now acknowledged that this scheme is too simplistic to explain the complexity of macrophage phenotypes *in vivo*. Signals for macrophage activation or polarization include molecules produced by other host cells (*e.g.*, chemokines and cytokines), invading microbes (*e.g.*, lipopolysaccharide), and the host tissue environment. In short, macrophages ingest and kill microbes, serve as antigen-presenting cells (APCs), survey tissues, and remove debris and dead or dying host cells in a non-inflammatory manner. Each of these processes is important for maintaining the healthy host.

DCs are tissue-resident phagocytes that function primarily as APCs and immunoregulatory cells. They originate from DC precursors in bone marrow or from circulating monocytes. DCs can be classified into at least three distinct subsets – classical or conventional DCs (cDCs), plasmacytoid DCs (pDCs), and monocyte-derived DC (moDCs) – based largely upon the presence of specific cell surface receptors and morphology. cDCs arise from common dendritic cell precursors and are distributed in many tissues of the body. These cells have a lifespan of ~ 1 week and are replenished continually. The primary function of cDCs is to present antigen to T cells. Thus, they often migrate to tissues enriched with T cells (*e.g.*, lymph nodes and spleen). Compared with macrophages, cDCs have a much higher (~ 100 -fold) capacity to stimulate naive T cells. pDCs also originate from bone marrow progenitor cells and are involved in the immune response to viral infection. moDCs are also known as inflammatory DCs and like cDCs, they present antigen to T cells. The extent to which each of these subsets functions as a phagocytic cell is incompletely determined, but phagocytosis has been best characterized in cDCs and moDCs.

Recruitment and Phagocytosis

Many of the fundamental mechanisms involved in recruitment, chemotaxis, and phagocytosis are shared among circulating phagocytic cells. Inasmuch as neutrophils are the most abundant phagocytic cell in circulation and in most acute inflammatory processes, and because these functions have been well-characterized in neutrophils, our discussion of recruitment and phagocytosis is focused largely on neutrophils. Notable exceptions for these processes in other phagocytes are indicated where appropriate.

Recruitment

Neutrophils are recruited rapidly from the bloodstream to sites of injury, infection, or other inflammatory process, and are typically among the first phagocytes to arrive at such sites. Monocytes are generally recruited later, after the peak of neutrophil recruitment, which is due at least in part to their role in removal of apoptotic neutrophils and tissue repair. Molecules known as chemoattractants are produced by host cells and invading microorganisms. Chemoattractants recruit phagocytes to infected or damaged tissues and include host chemokines, such as interleukin 8 (IL-8) and chemokine (C-X-C motif) ligand 1 (CXCL1) (previously known as GRO α), or microbial products, such as *N*-formylated peptides. A chemokine named monocyte chemoattractant protein 1 (MCP1) or chemokine (C-C motif) ligand 2 (CCL2) is also important for recruitment of monocytes to sites of inflammation. The migration of phagocytes from the bloodstream into tissues is termed extravasation.

Circulating phagocytes detect low concentrations of chemoattracts, which in turn upregulates surface expression of receptors important for extravasation. In neutrophils, upregulation of surface receptors is caused by fusion of receptor-laden secretory vesicles with the plasma membrane. There can also be partial fusion of specific granules with the plasma membrane, which further prepares neutrophils for chemotaxis and microbicidal activity. At this point during recruitment, neutrophils are primed for enhanced

to ingestion *per se*. In general, recognition and binding of microbes is mediated by pattern recognition receptors (PRRs), such as the Toll-like receptors, and receptors for host proteins known as opsonins. Although ligation of PRRs primes neutrophils for enhanced functions, including phagocytosis and production of ROS, this binding alone is typically insufficient to trigger phagocytosis. Invading microorganisms are typically coated with host opsonins, such as serum complement proteins and/or antibodies, that recognize specific molecules on the microbe surface.

Ligation of receptors for host opsonins, most notably those specific for serum complement and antibody, promotes phagocytosis directly (Fig. 2). Thus, it is perhaps not surprising that phagocytes express multiple receptors for serum complement (CR1 or CD35, CR3 or CD11b/CD18, and CR4 or CD11c/CD18) and antibody (e.g., Fc γ RI or CD64, Fc γ RII or CD32, Fc γ RIII or CD16, and Fc α RI or CD89). The binding of microbes with surface-bound complement and/or antibody triggers phagocytosis, which is facilitated by actin polymerization and cytoskeletal remodeling. The signaling mechanisms involved in phagocytosis and cytoskeletal rearrangement have been well-studied but are beyond the scope of this article. As microbes are sequestered within a newly forming vacuole (phagosome), phagocytes become fully activated (as is the case with neutrophils), and microbes are in turn exposed to plethora of antimicrobial agents.

Microbicidal Activity

Neutrophils utilize an extraordinary array of microbicidal mechanisms to destroy and remove infectious agents, and these mechanisms can be generally classified as being oxygen-dependent and oxygen-independent.

Oxygen-Dependent Microbicidal Activity (NADPH Oxidase)

Phagocytes generate microbicidal ROS through the activation of a multi-protein enzyme complex known as the NADPH oxidase. The phagocyte NADPH oxidase is expressed in neutrophils, eosinophils, basophils, mast cells, monocytes, and macrophages and plays an essential role in host defense against pathogenic microorganisms. Note, however, that the NADPH oxidase is regulated differently in various types of phagocytes. For example, monocyte/macrophages and neutrophils express the same NADPH oxidase components; however, NADPH oxidase responses differ significantly in these phagocytes. Activated monocyte/macrophages exhibit a gradual increase in ROS production which peaks about 1 h after stimulation, whereas the response in neutrophils is very rapid, peaking in 2–10 min, depending on the stimulus. In addition, monocytes are capable of mounting an additional response after recovery from the initial response, which is typically not the case for neutrophils. Lastly, stimuli that activate the monocyte/macrophage NADPH oxidase do not necessarily activate the neutrophil NADPH oxidase. These differences likely reflect the distinct roles played by monocyte/macrophages and neutrophils in chronic versus acute inflammatory responses, respectively. Eosinophils, on the other hand, generate a substantially greater NADPH oxidase response than other phagocytes, which is directed to the extracellular environment rather than into a phagosome, which may be important for their ability to defend against parasitic helminths. Finally, basophils have been reported to lack a functional NADPH oxidase.

It is generally accepted that the core NADPH oxidase enzyme complex is composed of five oxidase-specific proteins (p22^{phox}, p40^{phox}, p47^{phox}, p67^{phox}, and gp91^{phox}) and a small GTPase (Rac1/2) (Fig. 3). The nomenclature for the phagocyte oxidase-specific components includes the suffix *phox*, which refers to phagocyte oxidase. The one exception is gp91^{phox}, which is also known as NOX2. Overall, the *phox* proteins are highly conserved across species, confirming the absolute requirement for this system in

Fig. 3 Superoxide-generating NADPH-dependent oxidase. During phagocyte activation, cytosolic components of NADPH oxidase (p40 *phox*, p47 *phox*, p67 *phox*, and Rac) translocate to the plasma membrane or phagosome membrane and associate with the gp91 *phox*/p22 *phox* heterodimer known as flavocytochrome *b*₅₅₈. The assembled NADPH oxidase complex transfers electrons from NADPH in the cytosol (not shown) to molecular oxygen, thereby producing superoxide. See text for details. This figure was originally published in Quinn, M.T., Ammons, M.C., DeLeo, F.R., 2006. Clin. Sci. 111, 1–20. <https://dx.doi.org/10.1042/CS20060059>.

mammalian host defense. In resting cells, the NADPH oxidase proteins are segregated from each other (Fig. 3). Two of the proteins (p22^{phox} and gp91^{phox}/NOX2) form a 1:1 heterodimer known as flavocytochrome b, which is an integral membrane protein present in specific granule and secretory granule membranes. Note that flavocytochrome b contains all redox components required for transmembrane electron transport (*i.e.*, hemes and flavin). However, flavocytochrome b does not function independently, thereby insuring against inappropriate activation. Rather, the other oxidase protein cofactors listed above, which are located in the cytosol of resting cells, are absolutely required for enzymatic activity, presumably to initiate or facilitate the electron transfer process. The phagocyte NADPH oxidase is activated when cells encounter a variety of soluble and particulate stimuli, including specific cytokines, chemokines at high concentrations, microbes and microbial products, viruses, and other foreign antigens.

Depending on the stimulus, NADPH oxidase assembly and activation can occur at the plasma membrane (*e.g.*, activation by soluble stimuli, such as cytokines or N-formyl peptides) or in the phagosomal membrane (*e.g.*, activation following phagocytosis of a pathogen or foreign antigen). During activation, flavocytochrome b becomes associated with the phagosome or plasma membrane through granule or vesicle fusion. Concurrently, the cytosolic oxidase proteins and GTPase participate in an intricate sequence of activating events, including phosphorylation and intramolecular protein:protein binding interactions that culminates in translocation and association of the cytosolic proteins with flavocytochrome b to form the active enzyme (Fig. 3).

The active NADPH oxidase enzyme catalyzes the transfer of electrons from cytosolic NADPH to O₂, resulting in the formation of extracellular or intraphagosomal superoxide anion (O₂^{•−}). This results in a rapid and substantial increase in phagocyte O₂ consumption, which is known as the respiratory burst. Although high concentrations of O₂^{•−} can accumulate in phagosomes where the pH is low and can be directly toxic to some pathogens by virtue of the ability to oxidize iron-sulfur clusters present in bacterial enzymes, it is generally thought that O₂^{•−} represents the precursor to more powerful microbicidal oxidants that play more prominent roles in pathogen killing. Note, however, that the initial generation of O₂^{•−} is absolutely essential, as demonstrated by chronic granulomatous disease (CGD), which is a rare genetic disease resulting from defects in NADPH oxidase component proteins. The majority of CGD mutations that have been identified result in defective gp91^{phox}/NOX2, p22^{phox}, p47^{phox}, or p67^{phox} and result in absent or substantially reduced O₂^{•−} production. As a result, individuals with CGD experience severe, recurrent bacterial and fungal infections and can develop granulomas that form from accumulated phagocytes containing ingested bacteria. In addition to their impaired microbicidal function, CGD phagocytes exhibit abnormal apoptosis/turnover, which is also due to defective NADPH oxidase function.

At physiologic pH, O₂^{•−} is rapidly converted to hydrogen peroxide (H₂O₂) by spontaneous or enzymatic dismutation, which is catalyzed by superoxide dismutase (SOD). This abundant antioxidant enzyme plays an important role in protecting cells and tissues from excessive ROS. Additional antioxidant enzymes are also present to detoxify H₂O₂, including catalase and glutathione peroxidase. In addition to the production of ROS, phagocyte activation also results in the release of cytoplasmic granule contents into the phagosome, including high concentrations of myeloperoxidase (MPO). MPO is also found in monocytes, but its expression is normally lost when monocytes mature into tissue macrophages. On the other hand, MPO can be found in macrophages during certain disease states. Importantly, MPO utilizes H₂O₂ and chloride ions to form hypochlorous acid (HOCl), which is one of the most potent microbicidal oxidants and can kill a wide spectrum of pathogens, including bacteria, viruses, and fungi. O₂^{•−} can also be converted into hydroxyl radical (HO[•]) and singlet oxygen (¹O₂[•]), which are potent oxidants, although their actual roles in phagocyte microbicidal activity *in vivo* are still being defined.

In addition to ROS, phagocytes also participate in the generation of reactive nitrogen species (RNS), including nitric oxide (NO[•]) and peroxynitrite (ONOO[•]). NO[•] is also important in innate immunity and has been widely implicated in the inflammatory response. Although it was originally proposed that NO[•] itself was directly cytotoxic, it is generally thought that the microbicidal effects of NO[•] are due to the formation of ONOO[•], which results from the rapid reaction between NO[•] and O₂^{•−}. In fact, NO[•] can even out-compete SOD for O₂^{•−}, making this one of the fastest known reactions. OONO[•] can decompose to nitrate (NO₃) at physiological pH or, in the presence of an oxidizable substrate, ONOO[•] decomposition also yields nitrite (NO₂), which can be converted into additional toxic metabolites that are microbicidal. Although it is clear that significant concentrations of OONO[•] can be generated in inflammatory tissues, the actual source of NO[•] is still under investigation. Macrophages can generate NO[•]; however, the production of OONO[•] by human neutrophils *in vivo* has been a matter of debate, and it still remains controversial whether human phagocytes can actually generate enough NO[•] to account for the observed OONO[•] levels. However, since NO[•] is ubiquitously produced in the vascular system, it is also reasonable that NO[•] derived from endothelial cells can react with phagocyte-generated O₂^{•−} at sites of inflammation, resulting in ONOO[•] formation. In any case, it is clear that ONOO[•] plays an important role in host defense and has also been implicated in the pathogenesis of various inflammatory diseases.

Oxygen-Independent Microbicidal Activity

Although significantly diminished in capacity, phagocytes from individuals with CGD are still able to kill a variety of microorganisms. Thus, it is clear that phagocytes also utilize an array of oxygen-independent microbicidal mechanisms. For example, neutrophils express a variety of antimicrobial peptides and enzymes that are stored in azurophil and specific granules and lysosomes so that they can be rapidly mobilized to the phagolysosome upon engulfment of a pathogen.

In addition to their high levels of MPO, neutrophil azurophil granules contain three neutral proteinases (cathepsin G, elastase, and proteinase 3), which can degrade microbial components, including bacterial cell walls. Azurophilic granules contain about 1/3 of the total neutrophil lysozyme, which is contained in both the azurophil and specific granules, can cleave linkages in the peptidoglycan of bacterial cell walls and can cooperate with complement in bacterial permeabilization. Azurophil granules also

contain several cationic proteins with microbicidal activity, including bactericidal/permeability-increasing protein (BPI), which is able to permeabilize and kill Gram-negative bacteria, and the α -defensins, which are small (3–4 kDa) cysteine-rich peptides that can permeabilize and kill a range of Gram-negative and Gram-positive bacteria, fungi, and enveloped viruses.

Specific granules store unsaturated lactoferrin and lipocalin-2, which sequester iron away from bacteria in the phagosome to limit bacterial growth; transcobalamin II, which sequesters cyanocobalamin from bacteria; about 2/3 of the neutrophil lysozyme; collagenase, which cleaves type I collagen; phospholipase 2, which can degrade phospholipids; and hCAP-18, which is a cathelicidin that is cleaved by elastase to generate LL-37, a peptide that can kill Gram-negative and Gram-positive bacteria and may act synergistically with lactoferrin. Additionally, neutrophil specific granules contain a number of membrane proteins, such as flavocytochrome b, which are delivered to the plasma membrane or phagosomal membrane upon neutrophil activation, as described above.

Lysosomes contain acid hydrolases that are released into the phagolysosome after fusion of azurophil granules and are important for degrading a range of biomolecules necessary for bacterial growth. In addition, macrophages and neutrophils store cathelicidin-related antimicrobial peptides, which can damage and puncture microbial cell membranes. Note that neutrophils and macrophages utilize some common host defense mechanisms (*e.g.*, phagocytosis, NADPH oxidase, antimicrobial peptides), whereas other mechanisms are specific to only one type of phagocyte (*e.g.*, neutrophil granules). Thus, the phagocyte cell types have been adapted to their specific roles in host defense and work together to effectively eliminate pathogens.

Eosinophils are characterized by the presence of cytoplasmic crystalloid granules (also called secretory, specific, or secondary granules) that contain large stores of diverse, preformed cationic proteins, including eosinophil peroxidase (EPO), which is similar in function to MPO but catalyzes the formation of hypohalous acids with bromide and iodide (HOBr, HOI); major basic protein (MBP), which is involved in antiparasitic defense mechanisms as a cytotoxin for helminths and in immune hypersensitivity reactions; and eosinophil-associated RNases (EAR), which are RNase A-superfamily ribonucleases that have been proposed to play a role in defense against single-stranded RNA viruses. In addition, eosinophil granules contain a diversity of cytokines, chemokines, enzymes, growth factors, and receptors involved in innate immune defense processes. Interestingly, eosinophils mostly utilize selective secretion mechanisms to mobilize individual granule components (called piecemeal degranulation) rather than mass secretion of all contents at the same time, as appears to be the case with neutrophil granules. This allows eosinophils to respond appropriately to the stimulus or pathogen encountered.

Basophils are characterized by two types of granules (azurophil and specific granules), which represent stores of factors involved in the inflammatory response. As with eosinophils, basophil granule contents appear to be selectively mobilized by piecemeal degranulation. Basophil azurophil granules contain acid hydrolases and other enzymes. Basophil specific granules contain histamine, which is released in response to ligation of surface-associated Fc ϵ RI with IgE and increases capillary permeability to white blood cells and serum proteins; proteoglycans, such as heparin and chondroitin, which slow clotting and facilitate phagocyte recruitment; leukotrienes, such as leukotriene D₄, which also increases vascular permeability; and several cytokines. Notably, basophils secrete interleukin 4 (IL-4), which promotes T helper 2 (Th2) lymphocyte responses and is a key cytokine in the development of allergies and the production of immunoglobulin E (IgE).

Clearly, it is evident that phagocytes can utilize a wide array of forces to attack pathogens, and this represents a key component of the innate immune response. In addition, it is also clear that phagocytes require both oxygen-dependent and oxygen-independent microbicidal factors to be fully effective in their host defense functions. As seen in individuals with CGD, severe defects in oxygen-dependent microbicidal activity do compromise host defense; however, these individuals are still protected from a variety of pathogens, especially catalase-positive pathogens, through the implementation of oxygen-independent pathways. On the other hand, it has also been shown in protease-deficient animals that defects in oxygen-independent killing mechanisms also can also be detrimental to effective host defense.

Neutrophil Extracellular Traps (NETs)

Although the primary microbicidal mechanisms utilized by phagocytes are described above, more recent studies over the past 15 years have suggested an alternative defense mechanism whereby phagocytes trap and potentially kill microorganisms by forming neutrophil extracellular traps or NETs. They can be formed in response to infectious agents, inflammatory mediators, and/or under certain conditions, including non-specific osmotic cytolysis. NETs are composed of a web-like mesh of chromatin that is extruded from neutrophils undergoing NET formation in a process originally called NETosis. This mesh has been reported to be decorated with a variety of neutrophil proteins, including histones, MPO, elastase, cathepsin G, lactoferrin, and others. Thus, it appears that NETs can bind and sequester pathogens into a high local concentration of antimicrobial components in order to neutralize and kill these pathogens extracellularly but independent of phagocytic uptake. In addition to these microbicidal effects, NETs may serve as a physical barrier to prevent spread of the pathogens. It has also been proposed that NETs may keep potentially injurious granule proteases from diffusing away and damaging adjacent tissues.

NETosis requires ROS that are primarily produced by NADPH oxidase activation, although mitochondrial ROS production has been reported to substitute for the lack of an NADPH oxidase during basophil activation. In any case, ROS are required to trigger the activation and translocation of elastase from azurophil granules to the nucleus, where it degrades histones to disrupt chromatin packaging. This process is enhanced by MPO, which binds to nuclear DNA and works synergistically with elastase to decondense the chromatin, which is followed by rupture of the plasma membrane and extrusion of the DNA granule–protein complexes into the extracellular milieu to form NETs. Interestingly, this process does not seem to require MPO enzymatic activity, although the

mechanism is not clear. Finally, some stimuli, such as immune complexes, ionomycin and nicotine, and bacterial pore-forming toxins, trigger formation of NETs independent of ROS.

While NETs have been widely reported as an alternative mechanism for control and elimination of microbes, NETosis (as a cytolytic process) seems to be inconsistent with the high level of regulation exerted on neutrophil microbicidal functions because of the potential for host tissue damage resulting from inadvertent neutrophil lysis, release of cytotoxic agents, and post-lysis sequelae, such as inflammatory disorders. Indeed, NETs have been implicated in a number of inflammatory disorders, suggesting that neutrophil lysis and release of cytotoxic molecules may contribute pathological events in certain diseases.

Neutrophil Apoptosis and the Resolution of Inflammation

Many of the tissue-resident mononuclear phagocytes have an extended lifespan and/or self-renew, and the turnover rate for these cells is low. By comparison, there is enormous daily turnover of neutrophils ($\sim 10^{11}$ cells per day). During steady state or healthy conditions, neutrophils circulate in the bloodstream for a short period of time and then re-enter tissues. Inasmuch as neutrophils contain stores cytotoxic molecules that have potential to damage host tissues, it is critical that these cells are removed in a safe and timely manner. To that end, quiescent/unactivated neutrophils undergo constitutive or spontaneous apoptosis and are removed by macrophages. Importantly, as neutrophils undergo apoptosis, there is an accompanying decrease in their functional capacity (*e.g.*, reduced chemotaxis, phagocytosis, ROS production, and degranulation). This “shutdown” process likely limits unintended activation of cells marked for removal and/or helps prevent tissue damage should these cells lyse before removal. Uptake of apoptotic neutrophils by macrophages is termed efferocytosis and occurs in a non-inflammatory manner (Fig. 4(A)). These processes are integral to maintenance of host health and immune system homeostasis.

Phagocytosis-Induced Cell Death (PICD)

Neutrophil apoptosis and neutrophil turnover are altered during inflammatory processes, including following interaction with microbes. The short lifespan of neutrophils can be extended to some extent (a day or two during culture *in vitro*) by proinflammatory molecules, such as chemokines, cytokines, and some microbial products (*e.g.*, lipopolysaccharide). The ability of these molecules, many of which are priming agents, to delay the normal turnover of neutrophils is consistent with the increased host requirement for neutrophils during infection. On the other hand, phagocytosis alone can ultimately trigger neutrophil

Fig. 4. Neutrophil turnover is influenced microorganisms. (A) Normal neutrophil turnover by spontaneous apoptosis and their removal by macrophages. (B) Neutrophil phagocytosis-induced cell death (PICD). (C) Bacteria-mediated delay in neutrophil apoptosis. (D) Neutrophil lysis after phagocytosis. (E) Lysis of neutrophil by pore-forming toxins. (F) Neutrophil extracellular traps can form during neutrophil lysis. This figure was originally published in Kobayashi, S.D., Malachowa, N., DeLeo, F.R., 2017. *Front Cell Infect. Microbiol.* 7, 159. <https://dx.doi.org/10.3389/fcimb.2017.00159>.

apoptosis – a process that has been named phagocytosis-induced cell death (PICD) (Fig. 4(B)). PICD occurs several hours following phagocytosis – after neutrophils have become effete – and is therefore a post-phagocytosis sequela.

PICD requires NADPH oxidase-derived ROS produced at relatively high levels, which can be achieved following phagocytosis of multiple target objects or microbes. For example, phagocytosis of one or two individual Gram-negative bacteria is insufficient to trigger PICD. Rather, induction of PICD *in vitro* often requires high bacteria-to-neutrophil ratios (*e.g.*, 5:1 or 10:1), ratios that likely exist only at the infection nidus. This is an important distinction, since neutrophils at sites of infection may exhaust all microbicidal capacity and thereby become effete, which explains the need for these cells to undergo PICD and be removed by macrophages. This “ROS threshold mechanism” thus limits PICD in neutrophils that retain microbicidal activity. Neutrophils from patients with CGD have impaired or absent PICD, underscoring the importance of NADPH oxidase-derived ROS in PICD. CGD patients often develop large granulomas (presumably the result of unresolved inflammation), a phenomenon consistent with a defect in the resolution of the inflammation response (*i.e.*, a defect in PICD).

Neutrophil PICD likely represents an important component of the healthy resolution of infection and the inflammatory response.

Microbial Pathogens and Altered Neutrophil Turnover

Although the vast majority of bacteria and fungi are eliminated readily by neutrophils, some microbes possess the means to circumvent destruction by neutrophils. In contrast to macrophages, which are often parasitized by intracellular microbes, few microbes survive within neutrophils. This phenomenon is explained in part by the increased microbicidal activity of neutrophils compared with macrophages and the short lifespan of neutrophils, which is not an optimal period of time for replication of intracellular pathogens. Nevertheless, *Anaplasma phagocytophilum* is an obligate intracellular bacterium that delays neutrophil apoptosis (and fails to trigger PICD) and replicates within an endosome like-vacuole. In doing so, *Anaplasma phagocytophilum* causes human granulocytic anaplasmosis.

Alternatively, some bacterial pathogens, such as *Staphylococcus aureus*, can cause neutrophil lysis after phagocytosis (Fig. 4(D)). Although most ingested *S. aureus* are killed by neutrophils, some of these bacteria survive and ultimately cause neutrophil lysis. This interesting cytolytic process, which occurs within a few hours after phagocytosis of *S. aureus*, may be an important means by which the pathogen disseminates during human infections. Thus, the ability of microbial pathogens to alter normal neutrophil apoptosis and turnover can result in human disease (Fig. 4).

Glossary

Adsorption The physical adherence or bonding of organic and inorganic phosphate ions onto the surfaces of soil or mineral particles.

Assimilation (transitory immobilization) The process of incorporating nutrients into cellular biomass.

Authigenic Formed *in situ* rather than by having been transported or deposited in a location through secondary processes.

Chelation The reversible binding (complexation) of a ligand to a metal ion.

Decomposition The conversion of organic matter into simple inorganic compounds.

Diagenesis The process by which sediment undergoes chemical and physical changes during its lithification.

Eolian transport Advection of material via the atmosphere or wind.

Eutrophication Excessive nutrients in a body of water that causes a dense algal growth, followed by algal decomposition, anoxia, and impairment of the aquatic community.

Flux (phosphorus) Rate of flow of phosphorus per unit area, which has the dimensions $[\text{quantify}] \cdot [\text{time}]^{-1} \cdot [\text{area}]^{-1}$ (used for describing phosphorus turnover within a reservoir of flow from one reservoir to another).

Immobilization The process by which labile phosphorus is sequestered and removed from the environmental reservoir of bioavailable phosphorus for a period of time.

Inorganic phosphorus A class of chemical compounds that comprises those not existing in or derived immediately from living organisms (e.g., phosphate).

Mineral formation Processes in which anions react with cations in the environment to form insoluble precipitates.

Mineralization The conversion of organic matter into simple inorganic compounds by enzymes.

Mycorrhiza A symbiotic relationship between fungi and higher plants.

Nutrient limitation The cessation of photosynthetic biomass production in response to low availability of a physiologically important nutrient or nutrients.

Organic phosphorus A class of chemical compounds that comprises those existing in or derived from living organisms.

Orthophosphate Form of orthophosphoric acid (H_3PO_4) in which three protons have been lost (i.e., PO_4^{3-}).

Oxidation state The total number of electrons that an atom either gains or losses in order to form a chemical bond with another atom.

Phosphate Form of orthophosphoric acid (H_3PO_4); will be found as H_2PO_4^- or HPO_4^- at pH 4–9, the pH range most common in nature.

Primary production The conversion of radiant or chemical energy into organic matter.

Productivity The rate at which radiant energy is used by producers to form organic substances as food for consumers.

Redox cycling Chemical reactions whereby the oxidation state of a molecule is either increased (oxidation) or decreased (reduction).

Soil solution The liquid phase of soil, surrounding mineral particles, from which plants and microbes draw nutrients.

Solubilization The conversion of insoluble compounds into soluble compounds.

Weathering Processes by which rocks, minerals, and soils are transformed through physical or chemical processes.

Defining Statement

This review includes a discussion of the global phosphorus cycle, including sources, sinks, and transport pathways of phosphorus in the environment, microbially-mediated transformations of phosphorus and their genetic regulation, and a discussion of microbial responses to anthropogenic changes to the phosphorus cycle.

[☆]*Change History*: April 2018. Adina Paytan, Barbara J. Cade-Menun and Benjamin Van Mooy updated the text and further readings to this entire article and added new Fig. 2 (Examples of phosphorus containing compounds associated with microbes). Specifically, two new authors were added (Cade-Menun and Van Mooy), and two new sections included ("Microbially-Mediated Processes", "Immobilization", "Oxidation-Reduction", and "Plant-Microbe Interactions").

This article is an update of K.R.M. Mackey, A. Paytan, Phosphorus Cycle, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 322–334.

Introduction

Phosphorus is an essential nutrient for all living organisms, and the phosphorus cycle is an important link between Earth's living and non-living entities. The availability of phosphorus strongly influences primary production, the process by which photosynthetic organisms fix inorganic carbon into cellular biomass. Therefore, knowledge of the phosphorus cycle is critically important for understanding the global carbon budget and hence how biogeochemical cycles impact and are influenced by global climate.

The Global Significance of the Phosphorus Cycle

Natural assemblages of microbes have a critical role in the phosphorus cycle because they forge a link between phosphorus reservoirs in the living and non-living environment. Microbes facilitate the weathering, mineralization, and solubilization of non-bioavailable phosphorus sources, making phosphate available to microbial and plant communities and hence to higher trophic levels within the food web. However, microbes also contribute to immobilization of phosphorus, a process that diminishes bioavailable phosphorus by converting soluble forms to insoluble forms. The mechanisms of microbial involvement in these processes vary from passive (e.g., resulting from microbial metabolic byproducts) to highly regulated active contributions (e.g., the regulation of gene expression in response to environmental cues).

Microbially-mediated processes also link the phosphorus cycle to the carbon cycle and hence to global climate. During photosynthesis, photoautotrophs incorporate phosphorus and carbon at predictable ratios, with approximately 106 carbon atoms assimilated for every phosphorus atom for marine photoautotrophs. The phosphorus cycle therefore plays an important role in regulating primary productivity, the process in which radiant energy is used by primary producers to form organic substances as food for consumers, as in photosynthesis.

Because phosphorus is required for the synthesis of numerous biological compounds, its availability in the environment can limit the productivity of producers even when other nutrients are readily available. This fact carries important implications for the global carbon budget because the rate of incorporation (fixation) of carbon dioxide into photosynthetic biomass can be directly controlled by the availability of phosphorus; if phosphorus is not available, carbon dioxide fixation is halted. The intersection of the phosphorus and carbon cycles is of particular significance for global climate, which is affected by atmospheric carbon dioxide levels. Hence, through the growth of producers the phosphorus cycle contributes to the regulation of global climate.

In aquatic environments, photosynthetic microbes (i.e., phytoplankton) may comprise a substantial portion of the photosynthetic biomass and hence primary production. Marine and freshwater phytoplankton are characterized by extensive biodiversity and, as a group, inhabit an incredible number of different niches within aquatic environments. Phytoplankton, like other microbes, have strategies that enable them to adapt to changes in the amounts and forms of phosphorus available within their environment. For example, the production of phosphatase enzymes, which hydrolyze complex phosphorus compounds to simple, bioavailable inorganic phosphate, helps to mediate the mineralization of organic phosphorus compounds in surface waters, and allows cells to adapt when phosphate levels are low.

Recent estimates suggest that phytoplankton are responsible for as much as half of global carbon fixation, thereby contributing significantly to the regulation of Earth's climate. Phytoplankton productivity is strongly influenced by nutrient availability, and the nutrient that ultimately limits production depends on (1) the relative abundance of nutrients and (2) the nutritional requirements of the phytoplankton. With some exceptions, production in most lakes is limited by the availability of phosphorus, whereas limitation of primary production in the ocean has traditionally been attributed to nitrogen, another nutrient required by cells in large quantities. However, phosphorus differs from nitrogen in that the major source of phosphorus to natural aquatic environments is the weathering of minerals on land that are subsequently introduced into water bodies by fluvial and eolian sources. In contrast, microbially-mediated nitrogen fixation, in which bioavailable forms of nitrogen are generated from nitrogen gas in the atmosphere, is a major pathway by which phytoplankton gain access to nitrogen (in addition to continental weathering). Because there is no phosphorus input process analogous to nitrogen fixation, both marine and terrestrial productivity over geological time scales are considered to be a function of the supply rate of phosphorus from weathering and the rate at which phosphorus is recycled in soil or aquatic systems. Accordingly, the phosphorus cycle influences phytoplankton ecology, productivity, and carbon cycling in both marine and freshwater ecosystems as well as those of natural and agriculture vegetation systems on land.

Characterizing and Measuring Environmental Phosphorus Pools

Occurrence of elemental phosphorus in the environment is rare, given that it reacts readily with oxygen and combusts when exposed to oxygen; thus, phosphorus is typically found in nature bound to oxygen. Phosphorus has the chemical ability to transfer a 3s or p orbital electron to a d orbital, permitting a relatively large number of potential configurations of electrons around the nucleus of the atom. This renders the structures of phosphorus-containing molecules to be quite variable. These properties are likely responsible for the ubiquity and versatility of phosphorus-containing compounds in biological systems.

Because phosphorus exists in many different physical and chemical states in the environment, specific definitions are needed to clarify different parts of the phosphorus pool. Chemical names reflect the chemical composition of the phosphorus substance in question, whereas other classifications are based on methodological aspects of how the substance is measured. For example, "orthophosphate" is a chemical term that refers specifically to a phosphorus atom bound to four oxygen atoms, forming the

orthophosphate molecule (PO_4^{3-}); at pH 4–9, the range typically found in nature, this would exist as H_2PO_4^- or HPO_4^{2-} (which are referred to as phosphate). In contrast the aquatic term “soluble reactive phosphorus,” (SRP), is a methodological term referring to everything that gets measured when a phosphate assay is performed (such as the molybdate blue or ascorbic acid method, described below). The majority of measured SRP comprises phosphate but other forms of phosphorus may be included as well due to experimental inaccuracy. Therefore, while SRP tends to closely reflect the amount of phosphate in a sample, the values may not be identical.

The most common assay for measuring SRP is the ascorbic acid method, which is approved by the US Environmental Protection Agency for monitoring phosphate in environmental samples. In this method, ascorbic acid and ammonium molybdate react with dissolved phosphate in the sample, forming a blue compound that can be observed visually or determined spectrophotometrically. Assays for measuring total phosphorus are also based on the ascorbic acid method but begin with a step to transform all phosphorus in the sample to phosphate (typically through digestion by heating the sample in the presence of acid). Following digestion, the sample is analyzed by the ascorbic acid method.

When phosphorus is measured in water samples, distinguishing forms that are part of particulate matter from those that are in solution is often useful. Phosphorus is therefore classified as “soluble” or “particulate”. Soluble phosphorus includes all forms of phosphorus that are distributed in solution and that pass through a filter with a given pore size (typically 0.45 μm), while the particulate fraction is the amount retained on the filter. Measurements of soluble phosphorus include both the “dissolved” and “colloidal” fractions. Dissolved phosphorus includes all forms that have entered a solute to form a homogenous solution. By contrast, colloidal forms include any tiny particles that are distributed evenly throughout the solution but that are not dissolved in solution. Soluble phosphorus is commonly reported because colloidal phosphorus particles are very small and differentiating between colloidal and dissolved phosphorus is methodologically difficult.

In soils, soil test phosphorus (STP) is a similar measurement to SRP, in that it measures labile or easily accessible phosphorus in the soil solution surrounding soil particles. There are several different methods to measure STP, each of which involves extracting a soil sample with an extractant, then measuring phosphate in solution with a colorimetric method such as the ascorbic acid method. The extractant will depend on soil pH, among other factors, and includes Bray P1 (dilute hydrochloric acid and ammonium fluoride), for low pH soils, and Olsen P (dilute sodium bicarbonate) for higher pH soils. Although STP is sometimes referred to as “available phosphorus”, this is not correct; these tests are designed to predict a crop response to phosphate fertilizer. Other methods to estimate soil bioavailable phosphate include placing anion exchange resins into soil for set periods of time. Total soil phosphorus is determined by digestion, as previously described for water, as is total plant phosphorus. The phosphorus contained in living soil microbial biomass is determined in extracts before and after soil fumigation with chloroform; the chloroform will kill any living organisms, causing them to release phosphorus into the extract.

When living organisms assimilate phosphorus into their cells, the resulting phosphorus-containing compounds are collectively called “organic phosphorus.” It must be stressed that this definition of the biologically-associated phosphorus as “organic phosphorus” is not identical to the chemical definition of organic compounds (e.g., containing carbon). For example, some intracellular biologically-synthesized compounds such as polyphosphate may not contain carbon bonding. The term organic phosphorus encompasses molecules within living cells as well as molecules that are liberated into the environment following decay of organisms. The major source of terrestrial organic phosphorus is plant material, which is released as vegetation decomposes, but microbial and animal sources also contribute significantly. In the marine environment, organic phosphorus comes from a variety of sources (e.g., plankton, fish excrement, advection from land, etc.), the relative contributions of which differ widely depending on location in the ocean. In contrast to organic forms, inorganic phosphorus compounds are not always directly of biogenic origin. Rather, they also include phosphate derived from the weathering of phosphorus-containing minerals, including soluble and particulate phosphate.

Although phosphate can be identified and quantified by simple colorimetric techniques, identifying and quantifying more complex phosphorus forms requires the use of advanced techniques and instruments, such as mass spectrometry or ^{31}P nuclear magnetic resonance (NMR) spectroscopy. These more complex phosphorus forms are discussed in detail in the section on Immobilization, below.

Phosphorus Sources, Sinks, and Transport Pathways

The phosphorus cycle encompasses numerous living and non-living environmental reservoirs and various transport pathways. In tracing the movement of phosphorus in the environment, the interplay between physical and biological processes becomes apparent. In addition to acting as reservoirs of phosphorus in the environment (as discussed in this section), microbes contribute to the transformation of phosphorus within other reservoirs such as in soil or aquatic environments (discussed below in Section “Microbially-Mediated Processes”).

Within the earth’s crust, the abundance of phosphorus is 0.10%–0.12% (on a weight basis), with the majority of phosphorus existing as inorganic phosphate minerals and phosphorus-containing organic compounds. A phosphate mineral is any mineral in which phosphate anion groups form tetrahedral complexes in association with cations, although arsenate (AsO_4^{3-}) and vanadate (VO_4^{3-}) may also substitute into the crystalline structure. Apatite is the most abundant group of phosphate minerals, comprising hydroxyapatite, fluorapatite, and chlorapatite (Table 1). These three forms of apatite share nearly identical crystalline structures, but differ in their relative proportions of hydroxide, fluoride, and chloride, each being named for the anion that is most abundant in the mineral. Phosphate minerals generally form in the environment in magmatic processes or through precipitation from solution

Table 1 Phosphate minerals and their chemical compositions. Apatite is the general term for the three minerals hydroxylapatite, fluorapatite, and chlorapatite

Apatite	$Ca_5(PO_4)_3(F, Cl, OH)$
Hydroxylapatite	$Ca_5(PO_4)_3OH$
Fluorapatite	$Ca_5(PO_4)_3F$
Chlorapatite	$Ca_5(PO_4)_3Cl$
Frankolite	$Ca_{10-a-b}Na_aMg_b(PO_4)_{6-x}(CO_3)_x-y-z(CO_3F)_y(SO_4)_zF_2$
Lazulite	$(Mg,Fe)Al_2(PO_4)_2(OH)_2$
Monazite	$(Ce,La,Y,Th)PO_4$
Pyromorphite	$Pb_5(PO_4)_3Cl$
Strengite	$FePO_4 \cdot 2H_2O$
Triphylite	$Li(Fe,Mn)PO_4$
Turquoise	$CuAl_6(PO_4)_4(OH)_8 \cdot 5H_2O$
Variscite	$AlPO_4 \cdot 2H_2O$
Vauxite	$FeAl_2(PO_4)_2(OH)_2 \cdot 6H_2O$
Vivianite	$Fe_3(PO_4)_2 \cdot 8H_2O$
Wavellite	$Al_3(PO_4)_2(OH)_3 \cdot 5H_2O$

(which may be microbially-mediated), and the chemical composition of the minerals depends on the ion or ions present in solution at the time of precipitation. For this reason, it is not uncommon for natural deposits of phosphate minerals to be heterogeneous, rather than composed of a single type of phosphate mineral. These natural deposits of phosphate minerals are collectively called “phosphorites” to reflect variations in their chemical compositions.

Soils and lake sediments are another terrestrial reservoir of phosphorus (Fig. 1). The phosphorus in recently formed soils will resemble the parent material on which the soil was formed, namely apatite and other phosphate minerals. Over time, the soil forming factors of climate (rainfall and temperature), topography and biota will transform phosphorus into other forms in conjunction with soil development. In warm, high-rainfall environments such as the tropics, cations will be lost with leaching

**Fig. 1** Schematic diagram of the phosphorus cycle showing phosphorus reservoirs (living in green boxes; non-living in blue boxes), physical transport pathways (blue arrows), and microbially-mediated transformations (green arrows).

and the soil pH will drop. Phosphorus forms in these soils will shift from associations with calcium and magnesium to associations with iron and aluminum. Phosphorus in soil is chemically controlled by precipitation with cations such as calcium and magnesium (here termed 'mineral formation'), by adsorption (the physical adherence or bonding of organic and inorganic phosphate ions onto the surfaces of soil or mineral particles) onto iron or aluminum oxyhydroxides, and by microbially-mediated mineralization of organic phosphorus. Mineralization is discussed in detail in the Section "[Microbially-Mediated Processes](#)".

Plants and microbes remove phosphate from the soil solution surrounding mineral particles. This creates a gradient, and the soil solution phosphate is replenished by desorption from mineral surfaces, by dissolving precipitated phosphorus forms or by mineralizing organic phosphorus. Plants draw inorganic phosphorus from lower soil depths and convert it to organic forms. These will be deposited on the soil surface and mixed into the soil by organisms such as earthworms. Over time, phosphorus will become stratified in soil in undisturbed natural ecosystems, with higher concentration and more organic forms at the soil surface and lower concentrations and more inorganic forms with depth. Land use can alter the forms and distributions of phosphorus in soils. Soils managed as croplands may have phosphorus added as fertilizers and pesticides, and will have phosphorus removed from crops, while animals grazing in pastures add phosphorus as urine and feces and remove phosphorus as they eat plant material. Management practices such as tillage will redistribute phosphorus forms within the profile, while fire can convert organic phosphorus to inorganic phosphate.

Marine and lake sediments also represent an important phosphorus reservoir, but because the physical and chemical factors affecting marine sediment differ considerably from those on land, some processes controlling phosphorus dynamics in aquatic sediments are different than for soils, although many are the same. In sediments, phosphate can be present in insoluble inorganic phosphates minerals (such as phosphorites), which are relatively immobile. Phosphate can also be adsorbed onto iron or manganese oxyhydroxides. The adsorbed phosphate can regain mobility in response to changes in the redox potential at the sediment-water interface and thus is considered more mobile. As in soil, phosphorus in aquatic detrital organic matter can also become remobilized as decomposition progresses through microbially-mediated processes.

Biota (i.e., microbes, plants, and animals) serve as another reservoir of phosphorus in the environment, as they assimilate phosphorus within their cellular biomass. Biota can contribute significantly to environmental phosphorus levels; for example, microbial communities contribute 0.5%–7.5% of total phosphorus in grassland and pasture topsoil, and up to 26% in indigenous forests. Microbes are also responsible for generating the myriad of organic phosphorus compounds found throughout the environment. In particular, microbes and primary producers play an important role in providing nutrition, including phosphorus, to higher trophic levels by making it biologically available (bioavailable). Phosphorus assimilation is a microbially-mediated process discussed in the "[Transitory immobilization](#)" section below.

Phosphorus is transported within the environment through various mass transfer pathways. For example, rivers are important in the phosphorus cycle as both reservoirs and transport pathways. Phosphorus that has weathered from minerals and leached or eroded from soils enters rivers through a variety of vectors, including dissolved and particulate forms in water from overland flow and in groundwater, and particulates brought by wind. Approximately 95% of phosphorus in rivers is particulate, and approximately 40% of that is bound within organic compounds. Rivers influence the distribution of phosphorus in soils and lakes by contributing or removing phosphorus, and riverine input is the single largest source of phosphorus to the oceans.

A number of outcomes are possible for phosphorus entering the ocean. Much of the phosphorus entering from rivers is trapped in near-shore areas of the ocean, such as continental margins and estuaries, through immediate sedimentation and biological assimilation. The remaining phosphorus enters the dynamic surface ocean, also called the euphotic zone, in which nearly all bioavailable phosphorus is sequestered within biota through primary production. Upon death of the organisms, a fraction of the biologically-sequestered phosphorus sinks below the euphotic zone and most of it is regenerated into bioavailable forms like phosphate by heterotrophic organisms. This recycling is part of the so-called "microbial loop". Physical processes such as upwelling and deep convective mixing draw the deep water, which in most parts of the ocean is nutrient rich compared to the surface waters, back into the euphotic zone where up to 95% of it is re-used in primary production. The remainder is removed from the ocean reservoir through particulate sedimentation, mineral formation (which may be microbially-mediated), and scavenging by iron and manganese oxyhydroxides, all of which deposit phosphorus as a component of ocean sediment.

The phosphorus cycle differs from the cycles of other biologically-important elements, such as carbon, nitrogen, and sulfur, in that it lacks a significant gaseous component; nearly all phosphorus in the environment resides either in solid or aqueous forms. The one exception to this rule is the volatile compound phosphine (PH_3 , also called phosphane), a colorless, poisonous gas formed in the environment from the breakdown of alkali metal or alkali earth metal phosphides with water. This process is poorly characterized and likely comprises various multistage chemical reactions. Microbially-mediated phosphine production can be a major source of the gas in engineered systems (e.g., sewage treatment facilities and constructed wastewater treatment wetlands) where organic phosphorus is abundant and reducing conditions are common, suggesting that microbes could also play a role in phosphine formation in natural systems (although direct enzymatic production of phosphine has not yet been identified). While phosphorus can exist as phosphine, the gas does not persist in the environment due to rapid autoxidation, preventing significant accumulation of phosphine in the atmosphere. Phosphine is therefore a minor component of the environmental phosphorus pool.

The absence of a significant gaseous phase does not eliminate the atmosphere as an important reservoir in the phosphorus cycle. When weathering and erosion of soil generate inorganic and organic particulate phosphorus, wind transports some of the particles from their source to a new location. These particles can include mineral dust, pollen and plant debris, insect fragments, and organic

phosphorus bound to larger particles. This distribution of terrestrial particulate phosphorus, termed eolian deposition, plays an important role in delivering nutrients to the oceans. In ocean waters where nutrient levels are naturally low, such as in the open ocean gyres where riverine inputs do not extend and significant upwelling does not occur, eolian deposition may comprise a large portion of the nutrient flux that is available for primary production. The eolian phosphorus flux to the oceans is approximately $1 \times 10^{12} \text{ g yr}^{-1}$, of which approximately half is organic and half is inorganic. The solubility, and therefore bioavailability, of the phosphorus in eolian particulate matter differs significantly depending on its source; however, estimates suggest that approximately 15%–50% is typically soluble.

Microbially-Mediated Processes

Immobilization

Immobilization refers to the process by which phosphorus is sequestered and removed from the environmental reservoir of labile phosphate for some time. Immobilization processes can generally be grouped into two categories. The first category, transitory immobilization or cellular assimilation, includes all processes that sequester phosphorus within living microbial cells and is rapidly reversible upon cell death, although some phosphorus may be incorporated into non-labile organic compounds. The second category, mineral formation, encompasses processes that generate phosphorus-containing minerals.

Transitory immobilization

Transitory immobilization, or assimilation, is an important mechanism of phosphorus sequestration in soil and aquatic environments. Within cells, phosphorus is incorporated in numerous essential biological-molecules and is required in larger quantities than many other elements. However, unlike other biologically important nutrients such as nitrogen and sulfur that must first undergo reduction prior to being incorporated into the cell, phosphorus remains oxidized before and after assimilation. Because mineralization of cellular material occurs rapidly following cell death, cellular assimilation of phosphorus into biological macromolecules leads to relatively short-term phosphorus retention in living cells where the duration is related to the characteristics of the microbial community in question, and to the nature of the compounds produced. Within the cellular reservoir, phosphorus is present as different compounds that serve various functions.

Complex phosphorus compounds are generally classified based on the bonding of phosphate (Fig. 2). Phosphomonoesters are compounds in which one phosphate group is linked to one carbon atom through an ester bond (through oxygen), phosphodiester have one phosphate group linked to two separate carbon atoms, each through an ester bond, and phosphonates have one carbon-oxygen-phosphorus bond replaced by a direct carbon-phosphorus bond. Phosphoramidates contain a nitrogen-phosphorus bond in place of a carbon-oxygen-phosphorus bond; however, these are rare compared to other phosphorus compounds, and are poorly studied for microbes, and will not be discussed further in this article. Polyphosphates have phosphate groups linked by energy-rich phosphoanhydride bonds.

Phospholipids, lipids in which a phosphate group has replaced one of the fatty acid groups, are phosphodiester. Lipids are generally hydrophobic; however, phospholipids are amphipathic, meaning that each molecule has a hydrophilic portion and a hydrophobic portion. The phosphate group is responsible for giving phospholipids their partially hydrophilic character, hence imparting a wide range of biochemical properties. In the cell, phospholipids are important in the formation of biological membranes and in some signal transduction pathways. The cell walls of gram-positive bacteria such as *Bacillus subtilis* and *Staphylococcus aureus* contain lipoteichoic acid (LTA), which contain long chains of ribitol phosphate or glycerol phosphate. Gram-positive bacteria cause many human infections (e.g., staph infections), which is linked to LTA. Phosphonolipids have phosphonates attached to lipids instead of phosphates. Phosphonolipids are wide-spread in nature; one example is 2-acyloxyethylphosphonate, which has been isolated from blooms of the aquatic cyanobacterium *Aphanizomenon flos-aquae*.

Nucleotides are biological compounds consisting of a pentose sugar, a purine or pyrimidine base, and one or more phosphate groups. Nucleotides are the structural subunits (monomers) of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), and alternating bonds between the sugar and phosphate groups form the backbones of these nucleic acids. The phosphate groups form phosphodiester bonds between the third and fifth carbon atoms of adjacent sugar rings, imparting directionality to the molecule. In addition, nucleotides are present as several major cofactors in the cell (e.g., flavin adenine dinucleotide (FAD), nicotinamide adenine dinucleotide phosphate (NADP), etc.) that have important functions in cell signaling and metabolism.

Adenosine triphosphate (ATP) is a nucleotide that performs multiple functions of considerable importance to the cell and contains polyphosphate and phosphomonoester bonds. The primary function of ATP is to aid in intracellular energy transfer by storing energy that is generated during photosynthesis and respiration so that it can be used in other cellular processes that require energy (e.g., cell division and biosynthetic reactions). In the cell, phosphate can be assimilated in ATP through substrate-level phosphorylation, oxidative phosphorylation, photo-phosphorylation, and via the adenylate kinase reaction. ATP is also active in signal transduction pathways, where it can be used as a substrate for kinase enzymes in reactions that transfer phosphate groups to proteins and lipids, forming phosphoproteins and phospholipids respectively. Phosphorylation is an important and ubiquitous form of signal transduction in many organisms.

Inositol phosphates are phosphomonoesters and are complex molecules in which one to six phosphates are bonded with carbons on the inositol ring. Inositol phosphates with six phosphate groups, inositol hexaphosphates (IHP) are more common in

nature than those with fewer phosphate groups, and the best-known and studied of these is the *myo*-IHP stereoisomer phytate. This compound is widely distributed in nature because it is a storage compound produced by higher plants, especially in seeds. Phytate is a highly reactive compound that forms stable complexes with a variety of mineral cations, and so can accumulate in soils. There is no evidence that phytate is synthesized by microbes. However, other IHP stereoisomers have been detected in soils and lake sediments, including *chiro*-, *scyllo*- and *neo*-IHP, and are thought to be produced by microbes by direct synthesis or by microbial transformation of phytate.

Phosphonates are widespread in terrestrial and aquatic environments. However, their role is poorly understood, but the C-P bond is thought to be more resistant to degradation than the more common ester bonds. In addition, some microbially-synthesized phosphonates have anti-microbial properties, providing protection. Some of these have been developed for commercial use. For example, some soil *Streptomyces* species produce glufosinate (phosphinothricin), which is used as a herbicide, while other soil *Streptomyces* species produce fosfomycin, which is used as a broad-spectrum antibiotic. In oceans, dissolved phosphonates have been shown to comprise up to a quarter of all high molecular weight dissolved organic phosphorus. Although the microbial sources of phosphonates are not fully understood, two genera of cyanobacteria and one species of *Thaumarchaeon* have been definitively implicated.

Phosphorus immobilized within cells is considered transitory because many phosphorus compounds can rapidly reenter the reactive phosphate pool following cell death, through microbially-mediated mineralization processes. The immobilization of phosphorus via cellular assimilation is therefore relatively brief (i.e., within the lifetime of a cell) compared to other

processes in the phosphorus cycle, some of which occur over geological time scales. However, the strong adsorption to mineral surfaces in soils and sediments by some phosphorus compounds such as IHP stereoisomers and DNA will increase their immobilization.

Phosphate mineral formation

Phosphate mineral formation represents another phosphorus sink that is influenced by microbial activity; however, it encompasses processes other than cellular assimilation and short-term storage of phosphorus as biological molecules. In mineral formation (also called phosphogenesis), phosphate anions react with cations in the environment to form insoluble precipitates. Sediments that comprise significant amounts of phosphorus-containing minerals are called “phosphorites,” and may contain apatite, francolite, and other phosphorus minerals. Mineral formation is generally an important mechanism of phosphorus sequestration in marine environments, where the high seawater calcium levels facilitate microbially-mediated formation of insoluble phosphorites. The sequestration of phosphorus by this process retains (immobilizes) phosphorus for longer periods of time than does transitory immobilization.

In order for an insoluble mineral to form, the concentration of the ions forming the mineral should be high enough such that super saturation is reached, and equilibrium of the precipitation reaction is shifted toward the product. In addition, the physical and chemical characteristics of the environment must be conducive to precipitation of that mineral based on its solubility characteristics, and factors such as pH, redox state, and concentrations of co-occurring ions all influence mineral precipitation. The mineral should also be stable in the environment for mineral formation to constitute a long-term sink for phosphorus.

Mineral formation occurs both authigenically and diagenetically in the environment. Authigenic mineral formation is the formation of insoluble precipitates (minerals) *in situ* rather than by having been transported or deposited in a location through secondary processes. In contrast, diagenetic mineral formation is the alteration of existing minerals by chemical changes occurring after the initial deposition of a mineral (i.e., during or after burial and lithification). The primary type of diagenetic phosphorus mineral formation in marine environments is the substitution of phosphate into calcium carbonate minerals such as calcite or aragonite. Microbes contribute to this process by mineralizing organic phosphorus to reactive phosphate, which then substitutes diagenetically into calcium carbonate.

In authigenic mineral formation, microbes may generate reactive phosphate from the mineralization of organic phosphorus sources, and the resulting localized high phosphate concentrations favor precipitation of phosphate minerals. In soils, microbes convert organic phosphorus to phosphate, increasing its concentration in the soil and promoting formation of stable minerals such as apatite. In productive areas of the ocean, microbial mineralization of detrital matter at the sediment-water interface generates reactive phosphate, some of which reacts with seawater calcium to form phosphorite. (Reactive phosphate that does not contribute to mineral formation is available for biological assimilation by benthic microbes or may be reintroduced to the euphotic zone by diffusion and upwelling for use by phytoplankton).

The accumulation of phosphorus in microbial cells during transitory immobilization also contributes to mineral formation by increasing the pool of phosphate that could react with cations to form minerals. This is particularly important in anoxic areas of the ocean and soils where phosphate levels are low. Under oxic conditions where phosphate is more abundant, luxury uptake and storage of phosphate as polyphosphate molecules occurs in some microbes (e.g., *Pseudomonas* spp., *Actinobacter* spp.), as discussed above. Cells use the energy stored in polyphosphates to activate an alternative organic electron acceptor when conditions shift toward anoxia, freeing substantial levels of phosphate in the process. The sequestration and release of phosphate by the cell under oxic and anoxic conditions respectively represents a mechanism by which microbes contribute to mineral formation because it generates locally-elevated phosphate concentrations near the cells; these concentrations could be high enough to induce precipitation of minerals. Accumulation of phosphate within cells may also lead to phosphorus immobilization via mineral formation if phosphorus minerals are generated and stored within the cell. Intracellular formation of mineral apatite is an example of phosphorus immobilization that has been observed in some microbes (e.g., *Escherichia coli*, *Bacterionema matrucotii*) following incubation with calcium phosphate at a slightly basic pH. This process occurs in living and dead cells, suggesting that the locally-elevated phosphate concentrations within the cell help initiate apatite formation. Similarly, the formation of carbonate fluorapatite following cell death has been observed in Gram-negative rods, possibly pseudomonads, in coastal marine sediment, and is thought to be an important phosphorite formation process in locations where sedimentation rates are low.

Weathering

Rock material exposed to the atmosphere breaks down, or weathers, as the result of numerous environmental processes. Weathering processes are classified into two categories. In mechanical weathering, physical processes (including thermal expansion, pressure release, hydraulic action, salt crystal formation, freeze-thaw, and frost wedge events) cause deterioration of rock material without changing the chemical composition of the parent material. In contrast, chemical weathering causes deterioration by altering the chemical structure of the minerals from which the rock is made. Chemical weathering processes include dissolution, hydrolysis, hydration, and oxidation-reduction (redox) reactions. Living organisms can contribute to mechanical weathering by altering the microenvironments at the surface of the parent material (e.g., by increasing local humidity or forming bio-films on surfaces); however, most biological weathering processes are classified as chemical weathering because they chemically alter the composition of the parent rock material directly or indirectly. These biological weathering processes are also referred to as solubilization.

Solubilization

Inorganic phosphorus can occur in nature in soluble and insoluble forms. The solubility of the most abundant form of inorganic phosphorus, phosphate, is determined by the ambient pH and the cation to which it is bound as a mineral (e.g., K^+ , Ca^{2+} , Mg^{2+} , Fe^{2+} , Fe^{3+} , and Al^{3+}). Microbially-mediated phosphorus solubilization plays an important role in the conversion of insoluble phosphorus minerals to soluble forms of phosphorus. Solubilization directly benefits the microbes that perform it by providing the bioavailable phosphorus needed for growth. Similarly, the process benefits other organisms (including other cells and higher plants) from the surplus of solubilized phosphorus.

Production of organic and inorganic acids is the primary mechanism of microbial phosphorus solubilization. In this process, biogenic acids interact with phosphorus minerals to form phosphates, thereby bringing phosphorus into solution. Chemoautotrophic bacteria (e.g., nitrifying bacteria and *Thiobacillus spp.*) generate inorganic acids (e.g., nitric and sulfuric acid) by oxidizing ammonium and sulfur respectively, and these acids can liberate soluble phosphorus from apatite, the most abundant phosphorus mineral. Production of organic acids occurs in numerous microbial taxa and can also contribute to the solubilization of phosphorus minerals. Many higher plants can also produce organic acids in their rhizosphere (the area adjacent to plant roots) to solubilize phosphorus. Many organic acids, such as citrate, oxalate, lactate and 2-ketogluconate, are chelating compounds. Chelation is the reversible binding (complexation) of a ligand to a metal ion. Chelators increase the solubility of insoluble phosphate mineral salts by complexing the metal cations, thereby making dissolution of the salt more energetically favorable. In addition to acid production, microbially-mediated redox reactions contribute to phosphorus solubilization through the reduction of iron oxyhydroxides and associated ferric (Fe^{+3}) phosphate (strengite). In this process, dissimilatory iron reduction of ferric phosphates liberates soluble ferrous (Fe^{+2}) iron as well as the phosphate associated with it. This occurs under reducing conditions, such as in flooded, anoxic soils and in some benthic (e.g., the sediment surface and some sub-surface layers) aquatic environments. In another redox process, hydrogen sulfide (H_2S) produced by sulfur-reducing bacteria reduces the ferric iron in iron phosphate ($FePO_4$) to ferrous iron. In this reaction iron sulfide and elemental sulfur are precipitated, and phosphate is generated.

Mineralization

Plant and animal detritus in the soil and in particulate and dissolved forms in aquatic environments comprise a large reservoir of organic phosphorus. However, because complex phosphorus forms such as those bound to carbon are generally unable to cross cell membranes, most of the organic phosphorus from the detrital pool is not directly available to many living organisms. To become bioavailable, phosphorus bound to organic material must be converted to phosphate by mineralization, which is accomplished through the activity of a number of enzymes, many of which are produced by microbes. Because this process makes nutrients available that would otherwise be sequestered in unavailable forms, mineralization provides a vital link between the detrital pool and living organisms. It is estimated that approximately 70%–80% of microbes can participate in phosphorus mineralization. As in many enzyme-catalyzed systems, mineralization is encouraged by higher levels of available substrate; however, high levels of inorganic phosphate (the product) do not necessarily impede the reaction, and mineralization will often occur even if an abundance of phosphate is present. Ambient conditions favoring phosphorus mineralization include those that also favor mineralization of other elements, such as optimal temperatures and pH values for the specific enzyme; in soil, adequate but not excessive soil moisture is also required.

Enzymes involved in mineralization comprise a diverse group of proteins, called phosphatases, with a broad range of substrates and substrate affinities, and varying conditions for optimal activity. In addition, phosphatases can either be constitutively expressed by an organism (produced all the time), or facultatively expressed under conditions of low phosphate (and in some cases, low carbon). The microbial phosphatases can be classified into general broad categories such as phosphonatases, phosphomonoesterases and phosphodiesterases, or into more specific categories such as nucleases or phytases, depending on the compounds they will hydrolyze. Phosphomonoesterases catalyze reactions with phosphomonoesters. The reaction involves the hydrolysis of the phosphorus-carbon bond, generating a free phosphate molecule and an alcohol as products. Phosphomonoesterases are further classified as “acid” or “alkaline” based on their optimal pH ranges for maximum catalytic activity. Because of their ubiquity and importance in phosphorus mineralization, phosphomonoesterases are often referred to simply as phosphatases in the scientific literature, rather than by their full name, and context is often necessary to determine which group is being referenced. Therefore, a phosphomonoesterase with a pH optimum near 8 might be referred to as an “alkaline phosphatase” rather than an “alkaline phosphomonoesterase”. In soils, both acid and alkaline phosphomonoesterase activities are usually measured, although the pH optima for these enzyme assays will vary with soil pH in some but not all soils.

Phosphodiesterases hydrolyze phosphodiesters. Cleaving of a diester proceeds similarly to the monoester reaction, with water added across the phosphorus-carbon bond yielding phosphate and an alcohol. Once a phosphodiester has undergone hydrolysis, the resulting alcohol phosphomonoester may undergo another hydrolysis step, catalyzed by a phosphomonoesterase. Specific examples of phosphodiesterases include depolymerizing nuclease enzymes such as deoxyribonuclease (DNase) for DNA and ribonuclease (RNase) for RNA.

Inositol hexaphosphates such as phytate are specifically hydrolyzed by phytases, of which there are four subclasses differing in pH optima, cofactor requirements, or mechanisms of action. Because it is found in seeds, phytate is a common part of human and animal diets. However, humans and many animal species do not produce phytases. The six phosphate groups of phytate allow it to

sorb tightly to soils, and it can accumulate, especial when manure is applied to soils. Below pH 5, DNA can also sorb to soil minerals and accumulate because enzymatic mineralization will be restricted. A combination of organic acids to desorb phytate or DNA, followed by enzyme hydrolysis, will be required to release phosphate from these tightly sorbed molecules.

Because many phosphatase enzymes are synthesized in response to low environmental phosphate levels (i.e., when the cells experience phosphate limitation), phosphatase activity has been used extensively as a metric for determining the nutrient status of microbial communities in aquatic ecosystems. This is less common in soils, where microbes are generally more limited by carbon or nitrogen than phosphorus. The activity of phosphatase enzymes has been measured in many terrestrial, lake, and marine environments using a variety of methods, and numerous laboratory studies have also been conducted. In the environment, the bulk phosphatase activity of an entire microbial community is commonly measured by incubating soil, sediment, or water samples with a phosphate-bound substrate in which the hydrolytic product undergoes a color change that can be observed visually or spectrophotometrically, such as *para*-nitrophenyl phosphate (PNP) (Fig. 3(a) and (b)), phenolphthalein phosphate (PPP), glycerophosphate, and 5-bromo-4-chloro-3-indolyl-phosphate (Fig. 3(c)). In addition, measurements can be made fluorometrically for the substrates 3-o-methylfluorescein phosphate (MFP) and 4-methylumbelliferyl phosphate (MUP). Radiometric analyses can similarly be made using ^{32}P labeled glycerol phosphate (or an equivalent molecule). Chemical analysis of the hydrolytic products of glycerol phosphate and other bioenergetically important molecules has also been used to estimate phosphatase activity in bulk microbial populations.

A major drawback to measuring bulk phosphatase activity is that it provides limited information, if any, about which members of the microbial community experience phosphate limitation at the time of sampling. For aquatic samples, this can be addressed to some extent by size fractionating cells (as on a filter) prior to incubation with the substrate, thereby allowing phosphatase activity to be assigned to gross taxonomic classes of organisms. However, size fractionation introduces other obstacles for data interpretation, and results must be interpreted with care. For example, activity in different size fractions can be skewed by groups of bacteria that coalesce to form larger particles, although the individual cells are small and would otherwise be grouped with smaller size fractions. Studies with mixed populations of bacteria and green algae showed that 44% of the measured phosphatase activity was attributable

to aggregated groups of cells. Moreover, in the marine environment substantial phosphatase activity has been shown to persist for 3–6 weeks at 50% of initial levels in water samples filtered to remove particles. These observations suggest that phosphatases free in solution or bound to soluble organic material can contribute a significant amount of phosphatase activity, potentially leading to overestimates of cell-bound phosphatase activity in the small-cell size fraction. A difficulty common to both bulk and size fractionated samples is that phosphatases can persist for long periods of time without being bound to a living cell. It is not uncommon for microbial cells to retain phosphatase activity for months or years after being dried or preserved, including in dried soil samples, indicating that cell viability is not critical for maintaining phosphatase enzymes over these time periods, and dead cells may contribute to the overall phosphatase activity in a sample.

Several methods have been developed to overcome the limitations of bulk enzyme activity measurements by directly labeling cells when phosphatases are present. These methods allow phosphatase activity to be attributed to individual cells or taxa, allowing greater resolution of the phosphate status of organisms within a mixed community. In aquatic samples, direct cell staining with azo-dyes or precipitation of lead phosphate at the site of enzyme-mediated phosphate release have been used together with light microscopy to visualize phosphatase activity on individual cells. Similarly, enzyme-labeled fluorescence (ELF) labels individual cells with a fluorescent precipitate (ELF-97) following hydrolysis of the non-fluorescent substrate molecule (2-(5'-chloro-2'-phosphoryloxyphenyl)-6-chloro-4-(3H)-quinazolinone) at the site of the enzyme (Fig. 4).

Oxidation-Reduction

Phosphorus can be found in a broad range of oxidation states. Like nitrogen, which occurs just above phosphorus in the periodic table of elements, the valence electrons of phosphorus allow -3 , 0 , $+1$, $+3$ and $+5$ oxidation states. However only the $+5$ oxidation state, i.e., phosphate, is thermodynamically predicted to remain stable in aqueous solutions (including soil solution). Consequently, inorganic phosphate is nearly always the dominant form of phosphorus in the ocean, lakes, sediments, and soils. The phosphorus-containing organic compounds that generally account for the vast majority of cellular phosphorus, including DNA, RNA, and phospholipids, also contain phosphorus in the $+5$ oxidation state. While the geochemistry and biochemistry of phosphorus generally reflects the chemical characteristics of phosphorus in the $+5$ oxidation state, there are pools of phosphorus at reduced oxidation states (-3 , 0 , $+1$ and $+3$) whose roles on Earth remain to be fully elucidated. The contribution of inorganic

reduced phosphorus species from geochemical sources, which include primarily metal phosphides produced via lightning strikes or meteorite strikes, is quite small. Thus, microbes are regarded as the primary sources of reduced phosphorus species. Phosphine (PH_3), which contains phosphorus in the -3 oxidation state, is a gas produced in environments where organic matter is actively degraded, such as sewage treatment plants or rice paddies. Atmospheric phosphine concentrations are much higher on land than over the open ocean. Phosphite (HPO_3^{2-}), which contains phosphorus in the $+3$ oxidation state, has been observed in low concentrations in soils, lakes, wetlands and rivers. Recent laboratory innovations are making phosphite and hypophosphite (H_2PO_2^- ; $+1$ oxidation state) analyses more accessible to investigators, and a growing body of observations suggests that these two reduced inorganic phosphorus species may be more prevalent than once thought. The biochemical mechanisms by which microorganisms produce reduced phosphorus species are poorly understood. Thermodynamic calculations suggest that the direct reduction of phosphate to phosphite is prohibitively endergonic in the presence of water. Thus, if this process is indeed mediated by microbes, then it would require highly specialized enzyme systems that have yet to be identified. By contrast, the direct oxidation of phosphite is highly exergonic, and dissimilatory phosphate oxidation has been tied to the microbial sulfate and nitrate reduction and possibly carbon dioxide fixation.

Plant-Microbe Interactions

Like all organisms, phosphorus is an essential nutrient for terrestrial plants. However, unlike aquatic environments where both phosphorus and organisms are mobile, terrestrial plants are fixed in place and can easily deplete the labile phosphate in the rhizosphere (the zone surrounding plant roots). To ensure a continued supply of labile phosphate, relationships between higher plants and rhizosphere microbes have developed. Carbon is the nutrient most limiting to many soil microbes; plants release carbon directly into the rhizosphere by exuding simple sugars or high molecular weight compounds, or indirectly by root turnover. Rhizosphere microbes in turn can produce organic acids to release adsorbed or chelated phosphate, phosphatases to mineralize organic phosphorus, or hormones to stimulate the growth of roots and root hairs. The majority of higher plants also form symbiotic relationships with fungi called mycorrhizas. These vary depending on the plant and fungal species. Arbuscular mycorrhizas are endomycorrhizas, where fungi colonize root cells and extend hyphae beyond the rhizosphere to increase phosphate uptake. In ectomycorrhizas, fungal hyphae form sheaths around plant roots and do not enter plant cells. The fungi involved in mycorrhizas extend hyphae into the soil to access phosphate beyond the reach of plant roots and root hairs and may also transform phosphorus by producing enzymes and organic acids.

Genetic Regulation of Microbially-Mediated Processes

Microbially-mediated processes, including those involved in the phosphorus cycle, are the outcome of numerous biological pathways occurring in concert across diverse microbial communities. Even cursory observations of natural microbial communities demonstrate that while microbially-mediated processes influence and change the environment, the environment likewise shapes the activity of microbes, in many cases by providing feedback that either inhibits or enhances the processes. (An example of this type of feedback is the synthesis of phosphomonoesterase enzymes, many of which are only present during periods of phosphate deprivation but not when phosphate is abundant in the environment). Likewise, microbially-mediated processes can also be controlled indirectly by secondary factors (other than phosphorus) that influence growth and metabolism, such as the availability of oxidized nitrogen or sulfur in some chemoautotrophic microbes.

These processes, which are manifest in the environment as the combined outcome of activities from a diverse microbial community, are in fact a result of genetic mediation within single cells. The regulation of genes in response to environmental stimuli determines how a cell will respond to its environment, including if and how it will contribute to microbially-mediated processes in the phosphorus cycle. To understand gene regulation in greater detail, highly sensitive genetic and molecular methods have been developed. Under laboratory conditions, these methods have elucidated pathways important in the immobilization (i.e., phosphorus assimilation into cell biomass) and mineralization (i.e., phosphatase production) of phosphorus, as well as countless other pathways and processes.

In *E. coli*, two major phosphate assimilation pathways have been identified. The phosphate transport system (Pit), which comprises a hydrogen-phosphate symport powered by proton motive force, is expressed constitutively and provides the cell with sufficient phosphorus for growth when phosphate concentrations in the media are not limiting. When media phosphate concentrations drop below a threshold concentration, the high affinity phosphate specific transport (Pst) system becomes engaged. This system has a 100-fold greater affinity for phosphate than Pit, enabling the cell to acquire phosphate from a limited reservoir. Uptake of phosphate through Pst is an ATP dependent process (e.g., requires energy input from the cell).

Pst is activated as part of the Pho regulon, a group of operons that is expressed when phosphate levels are low. Activation of the Pho regulon is initiated through phosphorylation of the PhoB cytoplasmic protein which, in its phosphorylated state, is a transcriptional activator of the operons within the Pho regulon. In addition to Pst, the Pho regulon also includes genes encoding alkaline phosphomonoesterase (PhoA), outer-membrane porin proteins that facilitate diffusion of phosphate into the periplasm (PhoE), and proteins for the uptake and processing of glycerol-3-phosphate (*ugp* operon) and phosphonates (*phn* operon).

Metabolism of glycerol 3-phosphate is an interesting strategy for heterotrophic microbes, such as *E. coli*, because it is a potential source of both phosphate and carbon for the cell. However, when grown under phosphate-deplete conditions and

expressing *ugp* genes, cells are only able to use glycerol 3-phosphate as a phosphate source, not as a carbon source. For cells to grow with glycerol 3-phosphate as the only phosphate source, another carbon source must also be provided. The *ugp* system is less efficient when internal cell phosphate levels are high and is no longer expressed if external phosphate levels increase above a threshold level. Another system that is not part of the Pho regulon, the *glp* transport system, is regulated by external and internal glycerol-3-phosphate levels rather than phosphate concentrations. Unlike in the *ugp* system, glycerol-3-phosphate acquired by the *glp* system can serve as the sole source of carbon and phosphate for the cell. Both *ugp* and *glp* systems facilitate direct cellular uptake of glycerol-3-phosphate; however, each is regulated by different internal and external cues (i.e., phosphate or glycerol-3-phosphate levels) and has a different nutritional strategy (i.e., supplying phosphate alone versus phosphate and carbon together).

These two systems are an example of how microbes, by developing multiple inter-related pathways, can contribute to microbially-mediated processes in the phosphorus cycle under a range of environmental and physiological conditions.

Experimental evidence shows that the phosphate assimilation pathways in other heterotrophic bacteria are similar to those of *E. coli*, and many microbes are known to have portions of the Pho regulon. In particular, the alkaline phosphomonoesterase gene (*phoA*) and homologues have been identified in numerous microbial taxa, and although the primary function of the protein remains the same, factors that influence its expression and activity vary from organism to organism. The diversity of organisms and environmental conditions in which this gene exist allow microbially-mediated mineralization of phosphorus to occur in nearly every environment where microbes are found. For example, photosynthetic cyanobacteria in the genus *Synechococcus*, which populate freshwater environments, coastal waters, and vast areas of the open ocean, have the *phoA* gene along with many of the other genes encoded in the Pho regulon, highlighting the global ubiquity of microbially-mediated processes in the phosphorus cycle.

Metagenomic techniques have the potential to significantly increase our understanding of phosphorus mineralization, as well as other aspects of phosphorus cycling, in terrestrial and aquatic ecosystems. These molecular-based techniques sequence extracted RNA and DNA to accurately identify and quantify a large number of microbial genes. In addition to better identification of the microbial community in a sample, metagenomics can identify the microbial genes coding for various phosphorus cycling processes, such as phytase or phosphonate production. Metagenomics will only identify the presence and abundance of these genes, which can only give the potential gene activity; it does not indicate if these genes are actually active in a sample or ecosystem. However, these metagenomic results can be linked to measures of ecosystem processes, such as the enzyme activity measurements previously described, or to the presence of substrates such as phytate, identified and quantified by techniques such as ^{31}P -NMR spectroscopy.

Anthropogenic Alteration of the P Cycle: Eutrophication in Aquatic Ecosystems

As discussed above, microbes have an important role in nearly every aspect of the phosphorus cycle, and their activities help control the relative rates at which phosphorus is mobilized and immobilized within the environment. However, humans also influence the phosphorus cycle and alter the structure of microbial communities, sometimes causing devastating ecological consequences.

Post-industrial human activities, including deforestation, phosphorus mining, and agricultural practices, affect the phosphorus cycle by increasing the mobility of phosphorus in the environment and causing it to accumulate in soils and aquatic environments. Several factors contribute to the mobilization of phosphorus by these activities. Deforestation and mining expose phosphate (and other) minerals in rock and soil to the atmosphere, leading to increased rates of weathering and erosion. Some agricultural practices such as tillage can also increase soil erosion, while the localized elevation of phosphorus levels from application of fertilizers can be a large source of the anthropogenic phosphorus input into receiving water. Elevated soil phosphorus levels increase the amount of phosphorus in runoff and ultimately lead to the accumulation of phosphorus in lakes and estuaries. Livestock production for meat or dairy will produce manures containing high concentrations of phosphorus. When applied to soil as fertilizer at rates to meet plant nitrogen requirements, this will apply excess phosphorus that may be lost in runoff. Increasing human populations, both in cities and in rural areas, will increase phosphorus in human sewage that can enter water systems if not properly treated and disposed.

As a result of these practices, recent estimates suggest that the net storage of phosphorus in terrestrial and freshwater habitats has increased 75% over pre-industrial levels, and the total phosphorus flux to the ocean is 2-fold higher than pre-human levels. When phosphorus enters water bodies where phosphorus limits production, substantial changes in the microbial community occur. Reversal of phosphorus limitation leads to eutrophication, the rapid growth of bloom-forming phytoplankton, some of which are toxic or nuisance species (like *Pfiesteria* sp.) that are harmful to aquatic organisms and humans. As the bloom exhausts the supply of phosphorus, the phytoplankton senesce, sink to the bottom of the water body, and are decomposed by the heterotrophic microbial community. At depth, where light levels are low, photosynthetic phytoplankton are not able to balance the metabolic oxygen demands of the heterotrophs, and anoxia occurs in the bottom waters. Anoxia damages the benthic environment, leading to fish kills and harming benthic invertebrate communities. Loss of submerged aquatic vegetation, coral reef death, human shellfish poisoning, and a reduction in biodiversity are among the possible outcomes caused by microbial responses to the anthropogenic introduction of excess phosphorus to sensitive aquatic ecosystems. Eutrophication has been observed in many ecosystems, including fresh water lakes like Lake Erie, large estuaries like the Chesapeake Bay, and coastal areas like the hypoxic “dead zone” of the Gulf of Mexico.

Conclusion

Microbially-mediated processes in the phosphorus cycle forge a critical link between the geosphere and biosphere by assimilating phosphorus within biological molecules and contributing to chemical transformations of phosphorus in the environment. In addition to acting as living reservoirs of phosphorus, microbes also contribute to the transformation of phosphorus within other non-living reservoirs, such as rock, soils, rivers, lakes, and oceans. Microbially-mediated phosphorus transformation includes processes that increase the bioavailability of phosphorus in the environment, such as weathering, solubilization, and mineralization, as well as those that decrease its bioavailability, such as assimilation and mineral formation. These large-scale environmental processes are the outcome of numerous biological pathways occurring in concert across diverse environmental settings and microbial communities. Genetic diversity and finely-tuned regulation of gene expression allow microbes to adapt to harsh environments, and to contribute to the phosphorus cycle under numerous and diverse environmental conditions. Human alteration of the natural phosphorus cycle causes unintended consequences in microbial communities, and serious environmental, economic, esthetic, and human health problems are caused by microbial responses to the anthropogenic introduction of excess phosphorus to sensitive aquatic ecosystems.

Phototaxis in Archaea and Bacteria

Jon Riggs and Wouter D Hoff, Oklahoma State University, Stillwater, OK, United States

Introduction

Scope of this article. Phototaxis is the process in which an organism alters its motility in response to light stimuli. This phenomenon is widespread in biology, encompassing complex multicellular organisms, unicellular eukaryotes, bacteria, and archaea. Here we will provide an overview of phototaxis in bacteria and archaea (prokaryotes). We will describe the process and mechanism of phototaxis using a small number of well-studied model systems to illustrate its general principles. In general, phototaxis involves a photosensory pigment (**photoreceptor**) that captures the light and converts it into a biological signal, a **signal transduction chain** (see "Sensory Transduction in Bacteria") leading to the **motility apparatus** of the cell, and a resulting change in motility of the organism.

Some light-induced changes in motility that fall under the general umbrella of phototaxis have been reported in chemotrophs. Here, we will focus on phototaxis in photosynthetic (in the broad sense of this term, involving both chlorophyll-driven photosynthesis and retinal-driven photosynthesis) bacteria and archaea, in which the majority of phototaxis responses have been reported and studied. It should be noted that photoreceptors have been identified in a large number of phototropic and chemotrophic microorganisms, but these proteins trigger a range of biological responses other than phototaxis, particularly biofilm formation. Various cases of photoregulation between motile and sessile states of prokaryotes have also been reported. This article will focus on phototaxis responses in phototrophic bacteria and archaea. The biological function of these phototaxis responses in photosynthetic prokaryotes is to accumulate in illuminated areas that allow photosynthetic activity while avoiding areas containing light of an intensity and spectral quality that can cause damage to the photosynthetic machinery (or other chromophoric components of the cell).

Helpful similarities and surprising differences exist between phototaxis in prokaryotes and chemotaxis in *E. coli*. Studies of phototaxis responses in phototrophic prokaryotes have greatly benefited from analogies with *E. coli* chemotaxis (see "Bacterial Chemotaxis: Conservation and Variation on a Theme"). These studies on chemotaxis focused on populations of free-swimming single planktonic cells. Core concepts used to understand both responses are as follows. In a constant, homogeneous environment, the swimming behavior of cells follows a **random walk**. Cell motion is caused by the rotation of **flagella**, or in the case of archaea: the **archaellum** (see "Archaellum, Bacterial Flagella", and "Swimming and Swarming Motility") attached to flagellar motors that are driven by the proton motive force. With a certain constant probability, a cell will reverse direction of the rotation of its flagellum (or flagella; there is considerable taxonomic variability in the number and placement of flagella on the cell), causing a change in the direction of swimming. When cells experience a change in signal input (either a change in chemoeffector concentration or light intensity), the probability of reversing the direction of flagellar rotation is altered (either increased or decreased), causing a change in motility of the cell. This (relatively) fast **excitation phase** of the response is followed by a (relatively) slow **adaptation phase**. As a result of this adaptation process, the initial value of the probability for reversing the direction of the flagellar motor is recovered. This mechanism causes cells to respond only to changes in light intensity or chemoeffector concentration, *i.e.*, cells effectively determine the time derivative of the external signal. As a result, when cells happen to move in a favorable direction (with respect to changes in light or chemoeffector concentration), the probability of changing swimming direction is reduced, while movement into an unfavorable direction increases the probability of changing swimming direction. This **biased random walk** causes cells in a spatial gradient to move towards favorable areas.

Key proteins and molecular processes that achieve this mechanism have been identified in studies of bacterial chemotaxis, particularly **methyl-accepting chemotaxis proteins** (MCPs) that serve as receptors for chemoeffectors, **CheA**, a kinase associated with MCPs that autophosphorylates its conserved His residue in response to changes in MCP conformation, and **CheY**, a diffusible protein that receives phosphoryl groups from CheA at a conserved Asp residue. Depending on its phosphorylation state, CheY binds to the flagellar motor to alter its probability of changing rotation direction. These protein phosphorylation events trigger the excitation phase of the response. The adaptation phase of the response is based on changing the methylation level of the MCP, which is performed by the methyl transferase **CheR** and the methyl esterase **CheB**. A range of variations on this theme has been discovered to govern the chemotaxis responses in different prokaryotes (See "Bacterial Chemotaxis: Conservation and Variation on a Theme"). A number of these components also occur in the phototaxis signal transduction chains in prokaryotes (see below).

Two basic mechanisms for light detection in prokaryotic phototaxis have been derived from extensive studies on a range of bacteria and archaea: (1) responses that are initiated by the bioenergetic consequences (changed in redox potential of components and/or changes in the transmembrane proton motive force) of photoexcitation of the photosynthetic machinery, and (2) responses that are initiated by the photoexcitation of dedicated photosensory receptors. The use of dedicated photoreceptors follows the conceptual framework provided by *E. coli* chemotaxis. Phototaxis responses mediated through the bioenergetic consequences of photoexcitation of the photosynthetic machinery are distinct from that case.

Recent progress in bacterial phototaxis has revealed two exciting aspects that move beyond the classical conceptual framework provided by *E. coli* chemotaxis, and are discussed below. First, a growing body of evidence indicates that single bacterial cells are able

to detect not only temporal changes in the intensity of light, but also the actual direction of the light beam. Since differences in chemoeffector concentration at the two poles of the bacterial cell are widely believed to be too small to be biologically useful, such directional sensing does not occur in prokaryotic chemotaxis. Second, in addition to phototaxis of free-swimming cells, entire colonies of bacteria can exhibit phototactic movement during social mobility, in which all cells in the colony engage in a coordinated pattern of motion.

Nomenclature of phototaxis responses. Different systems have been used in literature to describe phototaxis responses in microorganisms. One prevalent approach is based on the analogy between chemotaxis in *E. coli* and phototaxis in bacteria and archaea. In this approach, in analogy to molecules that act as attractants and repellents (chemoeffectors) in chemotaxis, light can attract microorganisms in **positive phototaxis**, while it repels microorganisms in **negative phototaxis**. The application of this approach is best fitted to cases of prokaryotic phototaxis where cells detect changes in light intensity as a function of time, corresponding to the detection of changes in chemical concentrations as a function of time in chemotaxis, as is the case for the archaeon *Halobacterium salinarum* and the proteobacterium *Halorhodospira halophila*, described below. It should be noted that in these cases the cells are not able to detect the direction of the light, only temporal changes in the intensity of the light. The other approach distinguishes four basic types of phototaxis: (a) the photophobic (fear of light) response, in which an increase in light intensity triggers a change in swimming direction, repelling the cells from the light; (b) the scotophobic (fear of darkness) response, in which a reduction in light intensity triggers a change in swimming direction; (c) photokinesis, in which cells alter the speed of their motility in response to change in light intensity; (d) true phototaxis, in which cells respond to the direction of the illumination (as opposed to temporal changes in light intensity or a spatial gradient in light intensity).

Model Systems for Bacterial and Archaeal Phototaxis

Much of our understanding of phototaxis in bacteria and archaea has been obtained through studies on a relatively small number of organisms, which can be viewed as model systems for prokaryotic phototaxis. Below we summarize understanding of phototaxis in four of these organisms (Table 1), including information on the photoreceptors and signal transduction pathway leading to the cellular motility machinery.

- (1) ***Halobacterium salinarum*.** The archaeon *H. salinarum* (previously called *Halobacterium halobium*) plays a prominent role in the field of prokaryotic phototaxis since the entire phototaxis process, starting from photoreceptor excitation, proceeding through an associated signal transduction chain to the flagellum, and the resulting cellular responses has been studied in considerable detail from a structural, genetic, biochemical, biophysical, and cellular perspective (Fig. 1(A)).

H. salinarum is an extremely halophilic organism that can grow both aerobically and (under conditions of illumination and reduced oxygen tension) photosynthetically. It swims using its archaeellum, which morphologically appears as a flagellar bundle located at a single pole of the cell. It should be noted that evolutionarily the archaeellum is closely related to **type IV pili** of Bacteria. The multiple flagellar motors in a cell rotate in unison in a single direction. In the absence of tactic stimuli, cells spontaneously reverse their swimming direction every 5–50 s. Cell tracking software to analyze the motion of populations of *H. salinarum* cells allows the identification of changes in the swimming direction of each individual cell in view of the light microscopy used. This approach has been applied extensively to quantify the background level of the reversal frequency, its transient increase upon a repellent response, and its suppression upon an attractant response. Upon exposure to a repellent light stimulus, the cell is triggered to reverse the direction of flagellar rotation and thus its swimming direction. *H. salinarum* exhibits both positive and negative phototactic responses.

The photosynthetic and phototactic capabilities of *H. salinarum* are based on four different retinylidene proteins, in which the light-sensitive cofactor is **retinal**. The discovery of the light-driven proton pump **bacteriorhodopsin** (BR) triggered extensive

Table 1 Phototaxis responses in four model organisms

Organism physiology/taxonomy	Photoreceptor(s)/pigments	Motility system	Signaling pathway	Phototaxis responses
<i>Halobacterium salinarum</i> Archaeon (Euryarchaeota) Extreme halophile	SRI, SRII/retinal BR/retinal	Free swimming archaeellum (bundle at single cell pole)	HtrI/CheA/CheY pmf	Positive & negative
<i>Rhodobacter sphaeroides</i> α -Proteobacterium purple non-sulfur anoxygenic photosynthetic	Photosynthetic RC chlorophyll, carotenoids	Free swimming single flagellum on side of cell	? (involves redox signaling)	Mainly step-down
<i>Halorhodospira halophila</i> γ -Proteobacterium Extremely halophilic purple Sulfur anoxygenic photosynthetic	PYP/ <i>p</i> -coumaric acid Photosynthetic RC Chlorophyll, Carotenoids	Free swimming single flagellum at each cell pole	?	Negative (PYP) Positive (RC)
<i>Synechocystis</i> sp. PCC6803 Cyanobacterium oxygenic photosynthesis unicellular, freshwater	PixJ, Cph2/bilin photosynthetic RC chlorophyll, carotenoids	Twitching by Type IV pili	?	True phototaxis in social (colony) motility true phototaxis in single cells by cell lensing

Fig. 1 Summary of phototaxis in four model systems. The motility system, photoreceptors (with chromophores), and signal transduction pathways are indicated for *Halobacterium salinarum* (A), *Rhodospirillum rubrum* (B), *Halorhodospira halophila* (C), and *Synechocystis* sp. PCC6803 (D). Photoreceptors are indicated in color; these colors are the same for proteins containing the same chromophore, but are for illustrative purposes only and are not intended to reflect the absorbance spectra of the proteins.

studies of the photobiology of this microorganism, and this led to the discovery of three additional retinylidene proteins: the light-driven chloride pump halorhodopsin (HR) and two sensory rhodopsins (SRI and SRII) that cause distinct phototactic responses. SRII is also referred to as phoborhodopsin.

A cautionary note regarding nomenclature is that when BR was first discovered in *Halobacterium salinarum* (then called *Halobacterium halobium*), the Domain Archaea had not yet been recognized, and *Halobacterium* was taken to be a bacterium. Therefore, the newly discovered protein in this organism was called bacteriorhodopsin (not archeorhodopsin) based on its resemblance to animal rhodopsin. To complicate matters further, later a quite distinct bacteriorhodopsin-like protein was

discovered in actual bacteria (namely marine Proteobacteria). This protein, which functions as a light-driven proton pump and contributes significantly to planetary biological light harvesting, was named proteorhodopsin.

SRI has an absorbance maximum near 587 nm, while the absorbance maximum of SRII is near 487 nm. Photoexcitation of SRI triggers a positive phototaxis response towards photosynthetically active light, since BR has an absorbance maximum at 568 nm. Light absorbance by SRII causes a negative phototaxis response towards blue light. In addition, photoexcitation of S_{373} , the blue-shifted photocycle intermediate of SRI, triggers a negative phototaxis response. Thus, the single protein SRI is responsible both for positive phototaxis towards light around 590 nm and for negative phototaxis towards light around 370 nm. This constitutes a mechanism of color discrimination.

While most phototactic responses in *H. salinarum* are triggered by the two dedicated photoreceptors sensory rhodopsin I and II, mutants lacking these two photoreceptors still exhibit residual phototactic sensitivity. These are transmitted BR. These bacteriorhodopsin-based responses are likely mediated by a “protometer” that senses the transmembrane electrochemical gradient (**proton motive force** or pmf). The protein(s) constituting the protometer have not yet been identified.

While BR and HR are ion pumps that function autonomously in generating transmembrane ion gradients, the sensory rhodopsins function through interacting with an associated signal transduction chain. A seminal finding was the identification of **HtrI** for **Halobacterial transducer protein**, the signal transducer for SRI. Interestingly, HtrI is homologous to the highly studied methyl accepting chemotaxis proteins from *E. coli*. HtrI was first identified based on its reversible methylation during phototactic responses. Htr transducer proteins contain two transmembrane α -helices and a large intracellular domain that is active in downstream signaling to kinases and is methylated during signal adaptation. Each SR interacts with a dedicated Htr in the membrane, forming SRI-HtrI and SRII-HtrII signaling complexes. Photoexcitation of the SR-Htr complex alters interactions within the complex, such that a signal is relayed from the SR to the Htr. Interestingly in the absence of HtrI the SRI photoreceptor has transmembrane proton pumping activity. In the presence of HtrI this proton pumping activity is fully repressed. This observation suggests that the protein conformational change involved in transmembrane proton pumping is similar to that involved for signal relay from SRI to HtrI.

The signaling pathway linking the SR-Htr complexes to the archaeal flagellum also is very similar to that of *E. coli*, involving both protein phosphorylation and protein methylation. CheA and CheY proteins play key roles in the signal transduction chain downstream of Htr. While each of the two SRs is associated with a dedicated Htr protein, their signaling chains converge at the level of CheA.

A rich body of information is available on the structure and light-triggered molecular mechanism of these retinylidene proteins. All four proteins consist of a bundle of seven transmembrane α -helices (labeled A to G), and contain a covalently linked retinal chromophore embedded in this helical bundle. They share ~25% amino acid sequence identity, particularly in the retinal binding pocket. A wealth of structural data has been obtained on these proteins, including X-ray structures of SRII at 2.1 Å resolution and SRII in complex with the transmembrane part of its signal transducer HtrII at 1.94 Å.

The ability of photoreceptor proteins to absorb light above 300 nm is based the involvement of protein-bound light-absorbing cofactors, or **chromophores**. All four archaeal rhodopsins contain all-*trans* retinal that is covalently attached to a highly conserved Lys side chain *via* a protonated Schiff base linkage. The protonated Schiff base is fully enclosed by the protein matrix, and thus represents a buried charge, which is stabilized by electrostatic interactions with nearby charged residues. In BR the counterion for the protonated Schiff base consists of two negatively charged side chains (Asp85 and Asp96) and one positively charged side chain (Arg82). A similar situation – but with significant modifications – is found in the other archaeal rhodopsins.

Photoexcitation of photoreceptors triggers a **photocycle** that results in the biological function of the protein. Such photocycles are initiated by a photochemical event, followed by a complex series of thermal transitions. In the halobacterial rhodopsins, light triggers the ultrafast all-*trans* to 13-*cis* photoisomerization of the retinal chromophore on a time scale of 0.5–5 ps. This initial process involves relatively small changes in the structure of the retinal, in which the strain of fitting the 13-*cis* chromophore in the all-*trans* binding pocket is distributed over a number of bond angles. This strain provides the driving force for a series of thermal reactions that trigger proton transfer reactions and the formation of the active **signaling state** of the photoreceptor. Finally, thermal recovery during the reformation of the initial state completes the photocycle. The role of light-triggered proton transfer events in photoreceptors for driving the conformational changes that initiate signaling is a recurring theme. This cyclic chain of thermal transitions is referred to as a photocycle. The photocycle of BR and HR is completed in ~10 ms, and results in the transmembrane translocation of a proton and chloride ion, respectively. In the SRs the photocycle is significantly slower: recovery of the initial state of the receptor requires ~1 s. During this photocycle the protein is converted from its initial receptor state to a signaling state that is active in relaying a signal into the associated downstream signal transduction chain. The ~100-fold slower photocycle of the SRs difference matches the sensory function of the SRs: the lifetimes signaling state(s) generated during their photocycle need to be sufficient for efficient relay of a signal into the attached signal transduction chain.

The proton transfer pathway involved in the deprotonation and reprotonation of the retinal Schiff base during the photocycle of the archaeal rhodopsins has received significant attention. An important example is provided by SRII, in which Asp73 is the acceptor for the Schiff base proton during the photocycle. The proton transfer from the Schiff base to Asp73 disrupts the active site salt bridge between these two residues, an event that is thought to be central to the receptor activation process in SRII. An important observation was made for the D73N mutant of SRII. In this mutant the salt bridge between the protonated Schiff base and residue 76 is already disrupted before photoexcitation of the photoreceptor. The D73N

mutation results in the **constitutive activation** of SRII. This mutation is highly reminiscent of the E113Q mutation in human rhodopsin, which also results in constitutive signaling. Thus, the light-triggered disruption of an active site salt bridge is a general mechanism for the activation of rhodopsin photoreceptors.

A set of important and unique experiments has allowed the *in vivo* identification of the signaling states of SRI and SRII. This work involved the *in vivo* reconstitution of retinal-deficient cells with various retinal analogs that differentially alter the various time constants in the SR photocycles. By relating the effects that these analogs have on the photocycle kinetics with changes in the phototactic sensitivity of the cells towards light, the functional signaling states could be identified. These experiments provide direct experimental verification for the validity of the concept of the signaling state in the living cell.

- (2) ***Rhodobacter sphaeroides***. The purple non-sulfur anoxygenic photosynthetic α -Proteobacterium *Rhodobacter sphaeroides* (previously called *Rhodopseudomonas sphaeroides*) swims by means of a single flagellum located in the center of the long axis of the cell (not at the cell pole). This organism is important for the field of prokaryotic phototaxis because it exemplifies the role of the photosynthetic machinery in triggering phototaxis (Fig. 1(B)) and how more complex variants of the *E. coli* chemotaxis signaling components can be used to integrate a range of chemotactic and phototactic signals.

Movement of the cell is only mediated by flagellar rotation in the counterclockwise (CCW) direction. Cells switch (approximately every ~ 10 s) between swimming and intermittent stops of approximately 1 s, during which the flagellum does not rotate. The resting flagellar resetting bias (probability of rotating CCW) in non-stimulated cells is quite high (near 0.85). As a result, *Rb. sphaeroides* responds significantly more strongly to negative stimuli than to positive stimuli. Therefore, phototaxis in *Rb. sphaeroides* is dominated by a step-down response, in which cells respond to a drop in photosynthetically active light by transiently stopping flagellar rotation. Upon a sudden drop in light intensity, cells stop moving within approximately 1 s, and subsequently resume normal motion within approximately 5 s. This response occurs when *R. sphaeroides* moves towards an area of lower light intensity, not when it swims into the direction of higher light intensity.

The photoreceptor for this positive phototaxis response is the photosynthetic machinery. This light detection mechanism therefore does not involve a dedicated photoreceptor protein. Instead, the pigments triggering these phototaxis responses are the bacteriochlorophyll and carotenoid molecules in the photosynthetic apparatus (the **photosynthetic reaction center** (RC) and the light harvesting complexes). The mechanism of phototaxis relayed *via* the photosynthetic machinery is important, since it occurs in various purple photosynthetic bacteria, including *Rhodobacter sphaeroides*, *Rhodocista centenaria* (formerly *Rhodospirillum centenum*), and *Halorhodospira halophila* (see below), allowing them to accumulate in areas illuminated with photosynthetically active light.

Illumination initiates photosynthetic electron transport, and a presumed redox sensor then relays the signal to the flagellar motor. Thus, at the heart of this type of phototaxis is a **redox sensing** mechanism, and the redox sensor is coupled to the photosynthetic machinery by the photosynthetic electron transfer chain. The identity of the proteins involved in this redox sensing mechanism has not yet been identified. The genome of *Rb. sphaeroides* encodes a rich complement of genes involved in chemotaxis responses (including nine transmembrane (MCPs) and four cytoplasmic MCPs, four CheA proteins, and six CheY proteins). Though an unknown mechanism, the redox signal relaying the phototaxis signal reaches this complex set of Che proteins, where it is integrated with chemotactic signals.

- (3) ***Halorhodospira halophila***. The extremely halophilic purple sulfur anoxygenic photosynthetic γ -Proteobacterium *Halorhodospira halophila* (previously called *Ectothiorhodospira halophila*) exhibits both phototaxis towards photosynthetically active light triggered by the photosynthetic machinery and negative phototaxis towards potentially damaging blue light triggered by a dedicated photoreceptor: photoactive yellow protein (PYP) (Fig. 1(C)). *H. halophila* has two flagella, one on each of the tips of the cell and behaviorally its phototaxis responses resemble those of *H. salinarum*. PYP was identified as the photoreceptor for negative phototaxis in *H. halophila* based on the close resemblance of the wavelength dependence of this response matches the absorbance spectrum of PYP. However, because genetic tools have not yet been developed for this organism, the biological function of PYP remains to be confirmed. Its proposed function for negative phototaxis was strengthened by the absence of other photosensory proteins encoded in its genome. Studies on this organism are relevant because (1) they show how signals from the photosynthetic machinery and from a dedicated photoreceptor can be integrated, and because (2) PYP has developed into an important model system for the molecular mechanisms of photoreceptor activation and more generally for the biophysics of protein dynamics.

Upon its purification from *H. halophila*, the structural biology and biophysics of PYP has been studied extensively. The chromophore of PYP responsible for its yellow color is *p*-coumaric acid, covalently linked to a conserved Cys residue in the protein *via* a thioester bond. This represented the first time that *p*-coumaric acid was found as a protein cofactor, establishing PYP as a novel type of photoreceptor. The PYP photocycle is initiated by photoisomerization of this chromophore, and this event is followed by proton transfer and large protein conformational changes. Intramolecular proton transfer is a key part of converting light absorbance into large conformational changes in PYP, and this mechanism is likely to be of more general importance. The downstream components of the signal transduction chain associated with PYP remain to be identified.

The structure of the PYP from *H. halophila* has been determined at high resolution, revealing that PYP consists of a central 6-stranded β -sheet, flanked on both sides by α -helices. Interestingly, this structure is common to a large number of domains that are all involved in signaling and regulation. This family of proteins is referred to as **PAS domains**.

The PYP photocycle shows a striking resemblance to that of the archaeal sensory rhodopsins. This provides a striking example of convergent evolution, since the structure and chromophore of these two photosensory systems are entirely different.

While PYP is present in a number of Proteobacteria, it now also has been identified in organisms from the phyla Bacteroidetes and Spirochaeta. Studies on these PYP homologs have revealed considerable functional diversity. The PYP from *R. centenaria* (previously *R. centenum*) contains a PYP domain, a bacteriophytochrome module and a histidine kinase output domain with autokinase activity that is regulated by blue light.

- (4) *Synechocystis* sp. PCC6803. *Synechocystis* sp. PCC6803 is a unicellular, freshwater cyanobacterium that can perform both phototrophic growth by oxygenic photosynthesis, heterotrophic growth by glycolysis and oxidative phosphorylation in the dark. It is a widely studied and genetically accessible model organism for oxygenic photosynthesis. Like all cyanobacteria it lacks flagella. However, it exhibits twitching motility (See “Non-Flagellar Bacterial Motility”) that is driven by the retraction type IV pili. In this type of motility, cells move forward as these pili extend and attach to solid surfaces, followed by a retraction of the polymer back into the cell. In contrast to the archaeum and flagellum, which are driven by the transmembrane proton motive force, motility based on type IV pili is driven by ATP hydrolysis through cytosolic ATPases that are associated with the pili. Motility switches in *Synechocystis* likely involve the intracellular relocation of the motor ATPases. Gliding motility necessitates the added complexity of interactions between the pili and a variety of different surfaces. To enable their gliding motility, cells can secrete extracellular polysaccharides, which then forms “tracks” along the path of cellular movement. Such tracks aid in the phenomenon of **social mobility** because once a track is laid, other cells are likely to move along the same path. Therefore, movement by type IV pili along slime tracks is often involved in social mobility.

Synechocystis is capable of complex photoresponses. It can respond to a variety of light signals, depending on the color (spanning the range from UV to red), intensity, and direction of the light signal. Its photoresponses include photokinesis, true phototaxis, and concerted social movement of many cells (**community phototaxis**), in which an entire colony moves towards or away from a light source (Fig. 1(D)). Such phototactic movement of entire colonies has been referred to as community phototaxis.

While true phototaxis was reported for cyanobacteria, and for the motility of colonies of the purple photosynthetic bacterium *Rhodospira rubra*, this ability to sense the direction of light remained controversial for many years. Where the light gradients over a single cell were considered too small to generate a biologically useful signal, social phototaxis could involve a light gradient across the entire colony. While *Synechocystis* phototaxis is enhanced for clusters of cells, individual cells retain phototactic capability, and – remarkably – also are able to detect the direction of light: true phototaxis in a single bacterial cell. Recently, the mechanism of this phototaxis response was found to be based on the phenomenon that the spherical cells of *Synechocystis* acts as a very effective microlens that focuses light at the edge of the cell, providing an appealing physical mechanism for such light detection. The true phototactic ability of single *Synechocystis* then presumably is enhanced in the community phototaxis responses of this organism.

The photoresponses of *Synechocystis* are triggered by an impressive array of photoreceptors, including three bilin-binding proteins and two flavin-binding proteins (the BLUF protein PixD, and possibly a Cry-DASH photoreceptor). In addition, light absorption by the oxygenic photosynthetic machinery of *Synechocystis* can contribute to its photosynthetic responses. Because of this complex photosensory machinery for phototaxis, it has proven challenging to unambiguously unravel if these proteins are directly involved as photoreceptors that control mobility or play a more indirect role in the light regulation of motility.

Cph2, PixJ, and UirS in *Synechocystis* belong to the phytochrome superfamily. In general, phytochromes exhibit photochromism between two stable light inter-convertible species that in the classical case have absorbance maxima in the red and far-red region. These photoreceptors contain a multi-domain photosensory module and a signal transmitter module. Their photochemistry is based on a linear tetrapyrrole chromophore that is attached to a Cys residue *via* a thioether bond. In plant phytochromes the photosensory module is formed by an N-terminal PAS domain, a central GAF domain, and a C-terminal PHY domain. However, bacterial phytochromes exhibit variations in this domain architecture, attachment site, and absorbance spectra.

The Cph2 photoreceptor in *Synechocystis* is a complex multidomain protein that combines two photosensory domains that bind bilin chromophores and domains for the synthesis (GGDEF) and degradation (EAL) of the second messenger c-di-GMP. The N-terminal photoreceptor domain is formed by an unknotted GAF-PHY **phytochrome** that absorbs in the red/far-red region. The C-terminal **cyanobacteriochrome** module absorbs green/blue light. This protein provides light-dependent regulation of the cytosolic concentration of the second messenger c-di-GMP, which in turn controls cell motility. The light-induced increase in c-di-GMP inhibits type IV pilus-dependent motility, which switches the cell from a motile form to a non-motile form. Such light-triggered changes in lifestyle appear to be a more general phenomenon.

The membrane-bound PixJ photoreceptor combines a bilin-binding cyanobacteriochrome domain, two transmembrane helices, and an MCP domain. It exhibits characteristic reversible photoconversion between blue and green absorbing states. The crystal structure of the complete PAS-GAF-PHY sensory module of Chp1 from *Synechocystis* showed that the PAS domain forms an unusual tongue-like protrusion that seals the chromophore from the solvent. Based on the role of MCPs in *E. coli* chemotaxis and *H. salinarum* phototaxis, it is likely that the signal from PixJ feeds into a CheA/CheY type signal transduction chain leading to the type IV pili machinery and triggering a phototaxis response.

The third bilin-binding photoreceptor involved in *Synechocystis* phototaxis is the multidomain protein UirS. It combines transmembrane regions with a cyanobacteriochrome, an ethylene-binding domain, and a classic **two-component system sensor kinase** (see “Sensory Transduction in Bacteria”). The protein acts as a UV-A sensor *via* its cyanobacteriochrome module, which contains a phycocyanobilin linked *via* two cysteine residues and photoconverts between a UV-absorbing state and a green-absorbing state. Its downstream effector UirR acts as a transcription factor that modulates gene expression of proteins affecting the phototaxis machinery, particularly its balance between positive and negative phototaxis.

PixD is a flavin-containing protein with an absorbance maximum near 443 nm that belongs to the BLUF family of photoreceptors first identified through AppA from *Rhodobacter sphaeroides*. It contains an FAD chromophore embedded in a unique fold. Disruption of the gene encoding this protein has the unexpected effect of altering the positive phototaxis response of *Synechocystis* towards 660 nm light into a negative phototaxis response. Since PixD does not absorb light in that region, it may not function as the direct photoreceptor for phototaxis responses triggered by blue light. Possibly, PixD could be a sensor of light intensity and of weak blue light. The crystal structure of PixD has been reported at 1.8 Å resolution, revealing that it is stacked into two pentameric rings in a complex also containing PixE. While this complex is stable in the dark, it dissociates into monomers upon blue light excitation. Exactly how this intriguing effect contributes to the photobiology of *Synechocystis* remains to be elucidated.

Phototrophy and Phototrophs

Donald A Bryant, The Pennsylvania State University, State College, PA, United States; Montana State University, Bozeman, MT, United States

Introduction

Microorganisms are characterized on the basis of three important metabolic parameters: energy source, electron source, and carbon source for biomass production and growth. Phototrophs use light as an energy source, whereas chemotrophs derive energy from chemical sources. Lithotrophs and organotrophs obtain electrons for metabolic processes from inorganic or organic compounds, respectively. Finally, autotrophs or heterotrophs obtain the carbon required for biomass production from inorganic (C_i , CO_2 or bicarbonate or other C1 compounds like formate) or organic sources, respectively. These three parameters define four types of organisms: (1). Photolithoautotroph (e.g., cyanobacteria, purple sulfur bacteria, green sulfur bacteria); (2). Photoorganoheterotrophs (e.g., aerobic and anaerobic anoxygenic bacteria, heliobacteria); (3). Chemolithoautotrophs (e.g., hydrogen-oxidizing bacteria, sulfur-oxidizing bacteria, nitrifying bacteria, methanotrophs); (4). Chemoorganoheterotrophs (e.g., *Escherichia coli*, *Bacillus subtilis*, humans). This overview will consider microorganisms that use light as their energy source and will principally focus on those that use chlorophyll (Chl) for this purpose.

Two fundamentally different mechanisms for phototrophy occur among bacteria and archaea: retinalphototrophy and chlorophototrophy. Retinalphototrophs employ retinal-binding, rhodopsin-like proteins (e.g., bacteriorhodopsin, proteorhodopsin, halorhodopsin, or xanthorhodopsin) and light to produce stored potential energy in the form of ion gradients (either H^+ , Na^+ or Cl^-) across the cytoplasmic membrane (Fig. 1(a) and (b)). Chlorophototrophs use Chl- or bacteriochlorophyll (BChl)-proteins to perform light-induced redox chemistry, i.e., photochemistry, which leads to oxidation of a (B)Chl molecule and the reduction of an electron acceptor, either a quinone or an Fe/S cluster. Subsequent dark electron transfer reactions can produce stable reductants (quinols, reduced ferredoxin, or NADPH) as well as proton motive force that can be used to produce ATP. All photosynthetic organisms are chlorophototrophs, but not all chlorophototrophs are photosynthetic; many require organic compounds and thus are photoorganoheterotrophs. Chlorophototrophs occur in only seven bacterial phyla (Table 1).

Although its evolutionary origins are still enthusiastically debated, most scientists agree that the evolution of photosynthesis was one of the seminal events in the history of biology. Photosynthesis allowed cells to couple a plentiful source of energy, the sun, to the production of anabolic energy requirements, namely ATP and reducing power – necessary for carbon dioxide fixation and life. The essential catalysts of photosynthesis are photochemical reaction centers (RCs), which can transduce the energy of photons into chemical potential energy. Photosynthesis allowed cells to produce ATP and strong reductants by processes that were independent of geochemically derived hydrogen or existing organic compounds, regardless of their source (geochemical or biological). Thus, photosynthesis ultimately fueled a massive increase in biomass production and simultaneously produced oxidizing agents that allowed life to diversify. Ultimately, these processes led to oxygenation of Earth's atmosphere when cyanobacteria evolved the capacity for oxygenic photosynthesis about 2.5 GYA. This article will briefly describe the two types of phototrophs and their occurrence among archaea and bacteria, with an emphasis on Chl-based phototrophy.

Retinalphototrophs

Retinalphototrophs are widely distributed among bacteria, archaea and even eukarya. As noted above, these organisms produce retinal-binding, rhodopsin-like proteins that are light-activated ion gates. Light causes the all-*trans*-retinal chromophore (Fig. 1(a)) to isomerize to 13-*cis*-retinal, and subsequent conformational changes of the rhodopsin and restoration of all-*trans*-retinal chromophore cause the directional release of an ion into the periplasm or the cytoplasm. Retinal-proteins can produce H^+ or Na^+ gradients that can be coupled to ATP synthesis or nutrient uptake, and halorhodopsin can translocate Cl^- ions into the cytoplasm to help halophiles achieve osmotic equilibrium with their environments. Because retinal-binding proteins do not produce a reductant, retinalphototrophs cannot directly couple light energy to CO_2 fixation.

The first retinal-binding protein to be characterized was bacteriorhodopsin of the halophilic archaeon *Halobacterium* sp. (Fig. 1(b)). Halobacteria are normally aerobes, but because oxygen has limited solubility in the hypersaline conditions under which these organisms thrive, aerobic respiration is often limited due to oxygen limitation. Under anoxic conditions, the cells induce the synthesis of very large amounts of bacteriorhodopsin, leading to so-called purple membrane patches in the cytoplasmic membranes of the cells. Large numbers of these bacteria can occur in salt evaporation ponds, and their numbers can become so high that the ponds adopt the coloration of the organisms (Fig. 1(c)). Bacteriorhodopsin has seven transmembrane alpha-helices that form a 4+3 bundle in the membranes of cells (Fig. 1(b)). The retinal chromophore is covalently bound in a Schiff-base linkage to lysine-216 of the protein, and it intercalates between the alpha-helices near the middle of the membrane. A multi-step photocycle is initiated upon absorption of a photon. All-*trans*-retinal initially and rapidly isomerizes to 13-*cis*-retinal, and relatively minor conformational changes in the protein lead to release of a proton near the periplasmic side of the membrane. Further conformational changes and shifting of hydrogen bonds among tightly bound water molecules and amino acid residues lead to

Ponds containing the halophilic archaeon, *Halobacterium salinarum*, and the eukaryotic green alga, *Dunaliella salina*. *H. salinarum* produces purple membrane and bacteriorhodopsin in Cargill's salt evaporation ponds in San Francisco Bay near Newark, CA. Purple-colored ponds have higher sodium chloride concentrations than the orange-colored ponds, which are orange due to beta-carotene produced by *D. salina*. (Source: Wikipedia Commons, drold.jpg).

reprotonation of key amino acid residues as well as the return of the retinal to the all-*trans* configuration. Thus, the absorption of one photon leads to the directional release of one proton to the periplasm. The resulting proton motive force can be used to support ATP synthesis via ATP synthase or can be coupled to nutrient uptake. By comparison to chlorophototrophs, which can have antenna complexes with 100's to 1000's of antenna pigments, a disadvantage of rhodopsins is that they usually carry a single retinal chromophore and thus have small absorption cross-sections. Xanthorhodopsin, found in a few bacteria, partly overcomes this limitation by binding an antenna carotenoid molecule, Salinixanthin, that can transfer excitation energy to the retinal chromophore and thus increase the light-harvesting capacity of such proteins.

One of the earliest success stories in metagenomics was the discovery that many marine proteobacteria contain genes for bacteriorhodopsin-like proteins. Heterologous expression of one such protein in *Escherichia coli* established that these proteorhodopsins are functional light-driven proton pumps. Further metagenomics surveys have established that rhodopsin-like proteins are very widely distributed in nature, and have further established that these proteins are laterally transferred among archaea and bacteria at high frequencies. This may be due to the relative simplicity of such proteins. If an organism already has the capacity to synthesize β -carotene, then the acquisition of only two additional genes, β -carotene 15,15'-monooxygenase and the gene encoding the rhodopsin-like protein, are all that are required to gain the ability to use light to produce an ion gradient. Intriguingly, in phototrophic mat communities, some (mostly) anoxygenic chlorophototrophs also have the capacity to produce retinal-binding proteins. Although the significance of this observation is not clear, it seems that some chlorophototrophs are also retinal phototrophs.

Chlorophototrophs

Reaction Centers and Antenna Complexes

Chlorophototrophs are defined by their ability to synthesize Chls or BChls and RCs. Two types of RCs occur with some variations: type-1 and type-2. All RCs have either homodimeric or heterodimeric core structures that bind the key electron transfer cofactors. A pair of Chls or BChls, the "special pair," acts as either the primary or secondary electron donor; upon illumination, the special pair is oxidized and an electron is transferred to a Chl-like molecule, (Chl *a*, 8¹-OH-Chl *a*, pheophytin (Pheo *a*), BPheo *a* or BPheo *b*) and ultimately to a secondary electron acceptor that is either a quinone or a [4Fe-4S] cluster. Type-1 RCs produce a weak oxidant (i.e., an

Table 1 Properties of the major taxa of chlorophototrophic bacteria

Group	Phylum	Carbon metabolism	CO ₂ fixation pathway	(B)Chls	RC Type	LH	Oxygen	Genera # (#) ^a	Species # (#) ^a

oxidized Chl or BChl), and a strong reductant, a reduced [4Fe-4S] cluster. Type-2 RCs produce a strong oxidant (i.e., an oxidized Chl or BChl) and a weak reductant, a reduced quinone (quinol). Although there is no detectable sequence similarity for the polypeptides of type-1 and type-2 RCs, strong structural similarities indicate that these proteins evolved only once and that subsequent rounds of gene duplication and divergence led to the types of RCs that occur in modern chlorophototrophs.

Heliobacteria, *Chloracidobacterium thermophilum*, and chlorophototrophic members of the phylum *Chlorobi* have "homodimeric" type-1 RCs. The X-ray structure of the homodimeric RC of *Heliobacterium modesticaldum* was recently solved at 2.2-Å resolution. Surprisingly, the structure revealed that this "homodimeric" RC is actually a heterotetramer comprised of two PshA subunits, each of which have 11 transmembrane α -helices, and two PshX subunits. PshX has a single transmembrane α -helix and participates in binding two BChl *g* molecules and a carotenoid molecule. In total, the heliobacterial RC binds two carotenoids, 54 BChl *g* molecules, two 8¹-OH-Chl *a* molecules (primary acceptor), and four BChl *g'* molecules (two of which form the special pair and two of which are antenna pigments). Many but not all of the BChls occur in similar positions to Chls in the Photosystem I (PSI) RC of cyanobacteria, the second type of type-1 RC. Interestingly, the heliobacterial RC may not contain menaquinone, but the electron transfer chain terminates with an [4Fe-4S] cluster ligated between the two PshA subunits.

There are two families of type-2 RCs, both of which have heterodimeric structures. "Bacterial RCs" are found in chlorophototrophic members of the *Proteobacteria*, *Gemmatimonadetes*, and *Chloroflexi*, and Photosystem II (PSII) occurs in members of the *Cyanobacteria*. In anoxygenic bacteria, RCs are formed from two paralogous proteins, PufL and PufM; a third subunit, PufH, does not occur in members of the *Chloroflexi*. A fourth subunit, a membrane-bound tetraheme cytochrome *c*, is sometimes associated with these RCs. The PufL and PufM subunits each contain five transmembrane α -helices, which are structurally similar to the C-terminus of the core subunits of type-1 reaction centers. Type-2 bacterial RCs bind six pigment molecules – usually four BChl *a* (or sometimes four BChl *b*) and two BPheo *a* (or two BPheo *b*) molecules – one carotenoid molecule, and two quinones. The special pair transfers an electron sequentially to one of the two BPheo *a* molecules, to the first quinone (Q_A) and then to the second quinone (Q_B). Once

Q_B is doubly reduced and fully protonated, it leaves the RC and is reoxidized by ubiquinone:cytochrome *c* oxidoreductase; the reduced cytochrome *c* directly or indirectly reduces the oxidized special pair, completing a cycle that results in the production of protonmotive force for ATP production or other cellular work.

Cyanobacteria are unique among chlorophototrophic bacteria because they contain two types of RCs, PSI and PSII, which allow them to oxidize water. The core of PSI is formed by the PsaA and PsaB subunits, which are distant paralogs of PshH of heliobacteria. PSI is more complex than the homodimeric RCs of heliobacteria. PSI has 9 or 10 additional subunits and binds 96 Chl *a* molecules, 22 β -carotene molecules, two phyloquinones, and three [4Fe-4S] clusters. The core electron transfer chain comprises the special pair (a heterodimer of Chl *a* and Chl *a'*), four Chl *a* molecules, two phyloquinone molecules, and the F_X [4Fe-4S] cluster bound at the interface of the PsaA and PsaB subunits. PsaC, a small extrinsic, ferredoxin-like molecule, ligates two [4Fe-4S] clusters that form the terminal electron acceptors, F_A and F_B . PSI can reduce a soluble [2Fe-2S] ferredoxin or flavodoxin, which distributes electrons to ferredoxin:NADP⁺ oxidoreductase and to other cellular processes that require electrons (e.g., nitrate or sulfate reduction).

Like PSI, cyanobacterial PSII is far more complex than the bacterial RC. As crystallized, PSII contains 19 or 20 subunits, 35 Chl *a*, two Pheo *a*, 11 carotenoids, and two plastoquinones in addition to the Mn_4CaO_5 cluster that forms the active site for water oxidation. PsaA and PsaB, which form the core of the PSII RC, are distant paralogs of PufL and PufM, but phylogenetic analyses indicate that the core subunits of PSII arose from an independent gene duplication event. Until recently, no homodimeric type-2 RCs were known. However, the enzyme that catalyzes the four-electron oxidation of Chl *a* (or chlorophyllide *a*) to form Chl *f* in some terrestrial cyanobacteria is an homodimeric, type-2 photooxidoreductase that may have been an evolutionary predecessor to PSII.

The relatively small numbers of pigments associated with most RCs would not allow them to function efficiently at low and variable irradiance, and thus all chlorophototrophic bacteria except heliobacteria have extensive light-harvesting antenna complexes to increase substantially the number of chromophores associated with the RCs. Although RCs evolved once and then diversified, several independent solutions to the problem of light harvesting have evolved and are employed to optimize phototrophic metabolism. Antenna systems in chlorophototrophic bacteria are highly diverse, and only a few examples will be described here briefly. The light-harvesting complexes of *Proteobacteria* are ring-shaped, membrane-intrinsic, BChl-binding complexes comprised of two paralogous families of proteins with single transmembrane α -helices. Each subunit binds a single BChl molecule and the ($\alpha\beta$) protomer additionally binds one carotenoid molecule. The LH1 antenna complexes form ring-shaped arrays of about 15–17 protomers that surround the RC like a stockade. Many but not all *Proteobacteria* also produce LH2 antenna complexes that form ring-shaped octameric or nonameric complexes; the ($\alpha\beta$) protomers of LH2 each bind three BChls and one carotenoid. Because the ratio of LH2 to LH1 is not fixed, 200–300 BChl molecules can feed excitation energy to a single RC complex. LH2 complexes are not found in all chlorophototrophic *Proteobacteria*, *Gemmatimonas phototrophica* or in chlorophototrophic members of the *Chloroflexi*.

Green bacteria, which occur as members of the phyla *Chlorobi*, *Chloroflexi*, and *Acidobacteria*, have two defining properties: They synthesize BChl *c*, *d*, *e*, or *f*; and these special, self-assembling BChls form enormous, supramolecular, nanotubular arrays in light-harvesting antenna complexes known as chlorosomes. The characteristic green or brown colors of GSB result from the type of BChl present in chlorosomes (Fig. 2(i) and (j)). Green-colored strains have chlorosomes containing BChl *c* and/or *d*, and additionally contain chlorobactene and γ -carotene as major carotenoids (Fig. 2(i)). Brown-colored strains produce chlorosomes containing BChl *e* (or BChl *f*) and the bicyclic carotenoids, isorenieratene and/or β -isorenieratene (Fig. 2(j)). Self-aggregation of BChl *e* or *f* leads to a very strong absorption band at ~500–525 nm, which greatly enhances the ability of brown-colored GSB to absorb blue light. Brown-colored GSB are adapted to lower irradiances and are found at greater depths in aquatic environments than green-colored GSB. The chlorosomes of some members of the *Chlorobi* are the largest antenna structures known, and can contain up to 250,000 BChl molecules, along with substantial amounts of carotenoids and quinones. GSB cells contain up to 50 million BChl molecules, which collectively can account for ~30% of the cellular carbon. A protein-stabilized, lipid monolayer envelope surrounds the chlorosome. The major envelope protein is CsmA, a small, mostly α -helical protein that binds one BChl *a* molecule. CsmA forms dimers that assemble into a paracrystalline structure known as the baseplate in all chlorosomes. In members of the *Chlorobi* and *Acidobacteria*, CsmA interacts with another BChl *a*-binding protein, the trimeric Fenna-Matthews-Olson protein that binds eight BChl *a* molecules per monomer. The FMO protein in turn binds to the type-1 RCs in these organisms and ensures efficient energy transfer from the BChls of the chlorosome to the RCs. In chlorosome-containing members of the *Chloroflexi*, chlorosomes are associated with B808–866-RC complexes that are similar to LH1-RC complexes of purple bacteria, and *Roseiflexus* spp. have similar complexes.

Most chlorophototrophic members of the *Cyanobacteria* synthesize light-harvesting antenna proteins known as phycobiliproteins. Phycobiliproteins are a homologous family of brilliantly colored, water-soluble proteins that bind linear tetrapyrrole chromophores known as bilins. Together with assembly proteins known as linkers, phycobiliproteins assemble into supramolecular complexes known as phycobilisomes. Several structural classes of phycobiliprotein complexes are known. Typical cyanobacterial phycobilisomes can contain from ~500 to 1000 chromophores, which are usually associated primarily with PSII but can also transfer energy to PSI under some conditions. Phycobiliproteins absorb light in the visible range from about 500–650 nm that is poorly absorbed by Chl *a*; the phycobiliprotein content of PBS can be regulated by light wavelength in some organisms, allowing cells to acclimate to the wavelength composition of the incident light. Cyanobacteria can also synthesize integral membrane proteins that bind Chl *a* or Chl *a* and *b*; the IsiA protein can conditionally replace phycobiliproteins as antenna complexes under iron limitation. Other proteins paralogous to IsiA are the only light-harvesting proteins in some cyanobacteria that do not produce phycobiliproteins, such as *Prochlorococcus* spp. and *Prochlorothrix hollandica*. These Chl-protein complexes can associate with PSI, PSII, or both to improve light harvesting.

Cyanobacteria: Oxyphotobacteria

Members of the phylum *Cyanobacteria*, first described by Gomont in 1829, are aerobic, Gram-negative, oxygen-evolving chlorophototrophs (formerly known as blue-green algae and now sometimes called *Oxyphotobacteria*) (Fig. 2(a-d) and (f)). Although numerous exceptions are known (see below), most cyanobacteria synthesize Chl *a* as sole Chl and have three major complexes for harvesting and transducing light energy into chemical potential energy: PSI, PSII, and PBS. Cyanobacteria reduce carbon dioxide to biomass via the Calvin-Benson-Bassham cycle, and many produce the enzyme nitrogenase that allows the reduction of dinitrogen to ammonia. Many cyanobacteria undergo complex developmental cycles and produce specialized cells for nitrogen fixation (heterocysts), dispersal (baeocytes, hormogonia), and/or survival (akinetes). An interesting exception to these general properties is "*Candidatus Atelocyanobacterium thalassa*," which includes photoheterotrophic cyanobacterial symbionts of prymnesiophyte algae. These marine symbionts have substantially reduced genomes, 1.44–1.48 Mbp in different strains, which have lost genes encoding PSII, ribulose 1,5-bis-phosphate carboxylase/oxygenase (RuBisCO) and enzymes of other metabolic pathways, but have retained genes for nitrogenase and PSI, leading to nitrogen-fixing, specialist cells with anoxygenic photoheterotrophic metabolism – "symbiont heterocysts."

No consistent taxonomic scheme that integrates molecular, morphological, and ecophysiological observations currently exists for cyanobacteria. However, using polyphasic methods, nine cyanobacterial clades have recently been described: *Gloeobacterales*, *Synechococcales*, *Oscillatoriales*, *Chroococcales*, *Pleurocapsales*, *Spirulinales*, *Rubidibacter/Halothece*, *Chroococcidiopsidales*, and *Nostocales*, and the CyanoDB database currently lists >270 "validly described" genera (see "Relevant Websites section"). Genomic data and polyphasic methods that combine both molecular and phenotypic criteria have increased the number of major groups of cyanobacteria beyond the five sections suggested by Rippka and coworkers in 1979. Currently, the NCBI Taxonomy database groups nearly 18,000 entries into 8 orders, 49 families, 213 genera and approximately 800 species (see "Relevant Websites section"). Some authors have estimated that there could be up to 8000 cyanobacterial species, although it is unclear what definition of "species" was used to produce such estimates. It is clear that the authors were not considering ecologically distinct species, i.e., ecotypes, which would increase such estimates by many orders of magnitude.

The 3.4-Mbp genome of *Synechocystis* sp. PCC 6803 (Fig. 2(c)) was completely sequenced in 1996, and at that time, it was only the third completely sequenced bacterial genome. More than 550 cyanobacterial genomes, including representatives of all major

taxonomic groups, have now been sequenced. Consistent with their ancient origin and their metabolic, structural, developmental and physiological diversity, cyanobacterial genomes are highly diverse. Their sizes (1.6–13 Mbp) and GC contents (~30%–69%) have ranges similar to those of all bacteria. The large number of available cyanobacterial genomes should allow comparative analyses that can identify genes and metabolic modules associated with specific processes (e.g., heterocyst differentiation) or a specific ecological niche. An example of the latter is illustrated by findings associated with ability to grow in far-red light.

Terrestrial cyanobacteria often grow in environments that are strongly enriched in light wavelengths greater than 700 nm (e.g., soil, or under plant canopies where light is strongly filtered by Chl *a*). Many of these cyanobacteria can acclimate to these conditions, a process known as far-red light photoacclimation (FaRLiP; Fig. 2(a) and (b)). Comparative genomic analyses of FaRLiP organisms have revealed a highly conserved cluster of 20 genes, 17 of which are paralogs of genes encoding core subunits of PSI, PSII and PBS that are expressed in white light. The FaRLiP gene cluster additionally encodes three regulatory proteins: RfpA, RfpB, and RfpC. When cells capable of FaRLiP are grown in far-red light, a knot-less phytochrome (RfpA) phosphorylates a phosphate-shuttle protein (RfpC), which activates the transcriptional activator (RfpB) and thereby the expression of the genes of the FaRLiP gene cluster. Upon acclimation, cells synthesize far-red light absorbing pigments, Chls *d* and *f*, as well as specialized forms of allophycocyanin that absorb far-red light and assemble into specialized PBS-like complexes. The extensive remodeling of the photosynthetic apparatus to accommodate these changes allows cells to grow in far-red light. One of the genes in the FaRLiP gene cluster, *chlF*, encodes a highly divergent paralog of the PSII core subunit, PsbA. ChlF is a photo-oxidoreductase that synthesizes Chl *f* from Chlide *a* or Chl *a*. Examples of cyanobacteria that can perform FaRLiP are found in all major taxonomic groups, but no extensive metagenomic survey to identify terrestrial cyanobacteria that can perform FaRLiP has yet been performed.

Marine *Synechococcus* spp. and especially *Prochlorococcus* spp. are numerically dominant organisms of Earth's oceans and are believed to be responsible for ~25% of total global carbon fixation (and thereby dioxygen production). *Prochlorococcus* spp. were first described in 1988, and interestingly, unlike most cyanobacteria, they employ divinyl-Chl *a* and divinyl-Chl *b* in their photosynthetic apparatus and lack PBS (Fig. 2(d)). *Prochlorococcus* spp. also dominate genomic databases, accounting for ~30% of the sequenced cyanobacterial genomes. Twelve major clades of *Prochlorococcus* spp. are known, but examples of only five have been cultivated. Comparative physiological studies have shown that each clade is adapted to different light, temperature, and nutrient conditions. Furthermore, quantitative PCR analyses have shown that temperature, light, nutrients and competitor densities shape the populations of these organisms in their natural habitats. Comparative genomics of low-light and high-light-adapted ecotypes of *Prochlorococcus* and *Synechococcus* spp. reveal differences in genome size as well as genomic islands possibly responsible for specific adaptations to niches.

High-light-adapted ecotypes of *Prochlorococcus* spp. have small genomes, ~1.62–1.78 Mbp, but low-light-adapted ecotypes have larger genomes, ~1.7–2.6 Mbp. Marine *Synechococcus* spp. genomes are still larger, 2.2–2.86 Mb, although these genome sizes are still smaller than average bacterial (3.69±1.96 Mbp) or cyanobacterial genomes (5.33±3.69 Mb). Sequence analyses of worldwide samples has revealed that 100's of distinctive, individual genotypes can coexist in a milliliter of seawater. Each genome type has a unique gene complement, which presumably confers selective advantages to the individuals of that population. Remarkably, the global pangenome for *Prochlorococcus* spp., ~80,000 genes, is 40–50-fold larger than the gene content of an individual cell. Cyanophages enhance *Prochlorococcus* spp. diversity by transferring genes among the various ecotypes and by affecting natural populations by lytic infection cycles. Finally, mathematical modeling studies suggest that *Prochlorococcus* spp. and the dominant, co-occurring heterotroph, *Pelagibacter ubique* (SAR11), have a coevolved mutualism that maximizes their collective metabolic rate and carbon recycling through complementary carbon excretion and uptake pathways.

Although the *Synechococcus* spp. that inhabit the microbial mats of alkaline siliceous hot springs in Yellowstone National Park are only distantly related to these organisms in the open ocean, an analogous distribution of complex ecotypes with different genotypes associated with specific niches is also observed across physical and chemical gradients in these mats. The *Synechococcus* spp. in these mats have also probably coevolved with preferred phototrophic and non-phototrophic partners to build stable communities of similar composition that can be observed in mat communities associated with alkaline hot spring world-wide. Recent studies suggest that the microbial mats of Mushroom and Octopus Springs contain more than 17 chlorophototrophic species, including representatives of all seven phyla known to contain chlorophototrophs.

The structure of the enzyme RNA polymerase has been studied extensively in numerous bacteria. In all bacteria studied the enzyme has a core consisting of four subunits, $\alpha_2\beta\beta'$, and a fifth protein, σ , needed for promoter recognition and the initiation of transcription. Careful examination of the structure of cyanobacterial RNA polymerase revealed that the core consists of five subunits. Simply, the β' subunit in cyanobacteria is divided into two subunits, β' and γ . Remarkably, consistent with the idea that plant chloroplasts evolved from cyanobacteria, the core of RNA polymerase in plant chloroplasts consists of the same collection of subunits that occur in cyanobacteria.

Proteobacteria: Purple Bacteria

Chlorophototrophic *Proteobacteria* were first described in the middle of the 19th century, and they now represent the most metabolically diverse group of anoxygenic chlorophototrophs. Members of this major group of organisms have contributed significantly to our knowledge of the biochemistry and molecular mechanisms of photosynthesis and its regulation, and they have further been used to elucidate the biochemistry of sulfur metabolism. Their members occur in the *Alpha*-, *Beta*-, and *Gammaproteobacteria*, and are currently assigned to 11 orders, 16 families, and more than 330 species. Based upon their capacities

to oxidize sulfide and to form microscopically visible sulfur (polysulfide) globules, Winogradsky and Molisch were the first to recognize two distinct groups, “*Thiorhodaceae*” and “*Athiorhodaceae*.” Collectively described as “purple bacteria,” these two traditional groups are commonly referred to as purple sulfur bacteria (PSB; 29 genera and 74 species) and purple non-sulfur bacteria (PNSB; 28 genera and 96 species), respectively. Most purple bacteria produce BChl and RCs under anoxic conditions and are thus facultatively photosynthetic, often being capable of other metabolic modes, including aerobic respiration. Cultures of purple bacteria range in color from yellowish green to pink to reddish purple to dark brown because of the synthesis of large amounts of carotenoids in addition to either BChl *a* or BChl *b* (see Fig. 2(e)). Purple bacteria produce type-2 RCs and at least one light-harvesting complex, LH1, although many synthesize one or more additional types of BChl-binding LH complexes (e.g., LH2 and/or LH3). Purple bacteria fix carbon via the Calvin-Benson-Bassham cycle, and many are also capable of reducing dinitrogen when grown under anoxic conditions. A third major group of related organisms, the aerobic anoxygenic phototrophic bacteria (AAPB), were discovered in Japanese coastal waters in 1979. Unlike PSB and PNSB, in which oxygen suppresses the synthesis of BChl and the chlorophototrophic apparatus, AAPB produce BChl *a*, type-2 RCs, and carotenoids under oxic conditions (Fig. 2(m-p)). Most AAPB are strictly aerobic chemoheterotrophs, which supplement their energy production with chlorophototrophic energy production under oligotrophic conditions. An alternative and broader term for AAPB is aerobic BChl-containing (ABC) bacteria, which includes methylobacteria, *Rhizobia*, as well as some anoxygenic chlorophototrophs from other phyla.

Chlorophototrophic proteobacteria are abundant in highly diverse habitats, including soils, freshwater and marine aquatic environments, hot springs, hypersaline springs, soda lakes, hydrothermal vents, activated sludge and waste-water treatment systems. In addition to their ability to thrive in the presence of different oxygen concentrations, they may exhibit preferences for acidic or alkaline conditions and tolerate temperatures from below freezing to about 60°C. PSB are members of the *Gammaproteobacteria* that utilize sulfide as the preferred electron source for carbon fixation, and they can be found in most environments where light and sulfide occur together. Two families, *Chromatiaceae* and *Ectothiorhodospiraceae*, are distinguished by the location of polysulfide/sulfur globule deposition. In members of the *Chromatiaceae*, sulfur globules are formed inside the cells, while in *Ectothiorhodospiraceae*, the sulfur globules are deposited extracellularly. PNSB are facultatively anaerobic, anoxygenic chlorophototrophic members of the *Alpha*- and *Betaproteobacteria*. In spite of their common name, most PNSB are capable of sulfide oxidation, but they tolerate sulfide levels (~0.5 mM) about 10-fold lower than PSB. In addition to reduced sulfur compounds and hydrogen used by most purple bacteria, some strains can use ferrous iron [Fe²⁺], nitrite, or arsenite as electron donors for carbon fixation.

AAPB are a diverse group of aerobic chemoheterotrophs but are also anoxygenic chlorophototrophs that produce BChl under oxic conditions. *Roseobacter denitrificans* and *Erythrobacter longus* were the first organisms isolated from marine environments, and more than 80 species and a very large number of isolates are now known. The *Roseobacter* clade (*Alphaproteobacteria*, *Rhodobacteraceae*) is one of the most dominant clades in pelagic environments and can represent up to 30% of bacterioplankton communities. Overall, AAPB are the third most abundant chlorophototrophs in the ocean, and although members of the *Alphaproteobacteria* are most common, examples are now known among *Beta*- and *Gammaproteobacteria* as well. AAPB have been widely detected in other environments, including freshwater rivers and lakes. Numerous examples are also known for most extreme environments, including polar regions, hot springs, hypersaline springs, hydrothermal vents, and soils contaminated with toxic metal oxides. If one considers all organisms that have the potential to produce PufLM-containing type-2 RCs, then >500 genomes of potentially chlorophototrophic proteobacteria have now been sequenced. This currently includes representatives of about half of the described species of PSB and PNSB. These genomes characteristically have high GC contents (60%–74%) and are quite variable in size (~2.5–8.5 Mbp).

Roseobacter spp. are metabolically and physiologically versatile organisms that are also characterized by high genomic diversity. Although the type species, *Roseobacter litoralis*, is a chlorophototroph, chemoheterotrophic members are more numerous. AAPB synthesize BChl *a*, a variety of carotenoids, and type-2 RCs, and like other purple bacteria, have quite variable coloration (see Fig. 2(e) and (m-p)). Unlike other purple bacteria, AAPB are obligate chemoheterotrophs, although it is likely that most fix some carbon via anaplerotic reactions. Marine *Roseobacter* spp. are environmentally important because some degrade dimethylsulfoniopropionate, which is a major source of the climatically active gas, dimethyl sulfide, in the atmosphere.

Chlorobi: Formerly Green Sulfur Bacteria (GSB)

Most chlorophototrophic members of the phylum *Chlorobi* are green sulfur bacteria (GSB). GSB are strictly anaerobic, anoxygenic Gram-negative bacteria that are exquisitely adapted to low-light environments. GSB occur in the anoxic waters of lakes, inland seas and other stratified aquatic habitats – where sulfide and light co-occur. They are also found in circum-neutral hot springs, microbial mats, and anoxic sediments, where sulfide and/or thiosulfate are present but light levels limit the growth of other chlorophototrophs. Remarkably, GSB have been found at the chemocline of the Black Sea and near black smokers on the floor of the Pacific Ocean, environments where it is estimated that individual BChl molecules absorb only ~1–10 photons per day. Because they have a very limited capacity to assimilate organic compounds, GSB are obligately autotrophic and obligately phototrophic. They oxidize reduced sulfur compounds or ferrous iron and use their homodimeric type-1 RCs to produce very low potential ferredoxins, which are used for C_i fixation by the reverse tricarboxylic acid (rTCA) cycle.

Because of its rapid growth on thiosulfate, its fully sequenced genome and its capacity for genetic modification by natural transformation or conjugation, *Chlorobaculum* (*Cba.*) *tepidum* (formerly *Chlorobium tepidum*) has become the laboratory model for GSB (Fig. 2(i)). Much of the current physiological and biochemical knowledge of GSB derives from studies of this organism. GSB

genomes are small (1.97–3.13 Mb) and have moderate GC contents (44%–57%). Although synteny of chromosomal genes has not been highly maintained, GSB share a conserved core genome that includes all genes necessary for their anoxygenic chlorophototrophic lifestyle by sulfur oxidation and CO₂ fixation. The loss of synteny may be due to an apparently high proportion of genes acquired by horizontal gene transfer (HGT), which has been estimated to be ~24% for *Cba. tepidum*. Phage-mediated transduction is another plausible mechanism for HGT, and might be responsible for exchange of the *sox* cluster for thiosulfate utilization among GSB. Surprisingly, however, no phages infecting *Chlorobi* have yet been isolated. Nevertheless, a recent metagenomic study provided strong evidence that a lytic DNA phage acted as a vector for phage-mediated HGT of genes for BChl *e* and isorenieratene biosynthesis in the natural GSB population in Lake Ciso, a meromictic lake in Spain.

For nearly a century after their discovery in 1906 by Nadson, chlorophototrophic members of the phylum *Chlorobi* were considered to be synonymous with “green sulfur bacteria.” After nearly a century of isolation and study, anaerobic species associated with only four genera had been cultivated: *Chlorobium*, *Chlorobaculum*, *Prosthecochloris* and *Chloroherpeton*. The discovery of “*Ca. Thermochlorobacter aerophilum*” by metagenomic analyses, and the establishment of enrichment cultures from several hot spring mats for the cultivation of this unusual organism, broke the dogma concerning the physiological conformity of GSB that was based on decades of cultivation-based studies. Although “*Ca. T. aerophilum*” has a phototrophic apparatus very similar to that of GSB, it lives in an environment where oxygen tensions can reach 800% of saturation during the day. It cannot oxidize sulfur compounds, cannot fix carbon or nitrogen, and requires all three branched-chain amino acids for growth. Unlike all strictly anaerobic GSB, it relies on oxygen for important metabolic reactions, including (B)Chl biosynthesis. Further genomics studies have revealed that at least some of the early diverging members of this phylum are metabolically versatile, aerobic chemoorganoheterotrophs (e.g., *Ignavibacterium album*, *Melioribacter roseus*, and NICIL-2, an uncultured representative of the OPB56 clade), which are closely related to some members of the phylum *Bacteroidetes*. Phylogenetic analyses of the genomes of these early diverging members of the *Chlorobi* indicate that GSB now are restricted to the family *Chlorobiaceae* (class *Chlorobea*; order *Chlorobiales*).

GSB form syntrophic associations with other types of bacteria. For example, sulfide-oxidizing GSB are frequently isolated together with sulfate- or sulfur-reducing bacteria; together, these organisms can cycle sulfide and sulfate and organic carbon and C_i, producing a stable association. During syntrophic growth of a *Prosthecochloris* sp. with sulfur-reducing *Geobacter sulfurreducens*, direct intracellular electron transfer occurs in a process known as “syntrophic anaerobic photosynthesis.” *Prosthecochloris* sp. is independent of sulfide as an electron source and receives its electrons indirectly from the oxidation of organic matter by *G. sulfurreducens*. Although the partners are co-dependent in co-culture, the unknown mechanism(s) of electron transfer seems to be non-specific because the *Prosthecochloris* sp. strain is also able to receive electrons supplied by an electrode.

Phototrophic consortia are a particularly interesting type of symbiosis in which two types of bacteria combine to form a multicellular “holobiont” with quite distinctive properties. “*Chlorochromatium aggregatum*” and “*Pelochromatium roseum*” are examples in which the chlorophototrophic consortial partner can be either a green- or a brown-colored GSB, respectively, and the motile, heterotrophic partner is a betaproteobacterium from the candidate genus, *Symbiobacter*. Complete genome analysis of “*Chlorochromatium aggregatum*” suggests that this partnership may have arisen in spite of “chronic dysfunctionality,” because the “*Ca. Symbiobacter mobilis*” requires oxygen for important metabolic functions, while its GSB partner, *Chlorobium chlorochromatium*, is exquisitely sensitive to oxygen, especially in the light. “*Ca. S. mobilis*” has a single polar flagellum, and can confer swimming motility as well as chemotaxis and phototaxis upon the GSB partner (Note: all members of the *Chlorobiaceae* lack flagella). “*Ca. S. mobilis*” can sense light and sulfide, neither of which it can use, allowing taxis to locate favorable growth conditions for the consortia and allowing consortia to outcompete free-living GSB with which they co-occur. In return, the GSB partner apparently provides fixed carbon, fixed nitrogen, hydrogen and vitamin B₁₂ to its partner. “*Ca. S. mobilis*” lacks the genes for both known pathways for menaquinone biosynthesis, and it has an incomplete pathway for ubiquinone biosynthesis, yet its genome encodes electron transfer complexes that are known to require quinones as coenzymes for their function (e.g., type-1 NADH dehydrogenase, succinate dehydrogenase, and cytochrome *bd* quinol oxidase). *Chl. chlorochromatium*, which can be cultivated independently from its partner, clearly can synthesize menaquinone. Minimally, menaquinone must be provided to “*Ca. S. mobilis*,” but bidirectional exchange of menaquinone and menaquinol would allow oxidation of menaquinol driven by photosynthetic C_i reduction, directly coupling the energy metabolism of “*Ca. S. mobilis*” to the photosynthetic productivity of its partner. The two cell types are extensively connected by numerous “periplasmic tubules,” which suggests that the two organisms may share a common periplasmic space – and therefore share a common proton gradient for ATP synthesis.

Chloroflexi: Filamentous Anoxygenic Phototrophs (FAPs)

The phylum *Chloroflexi* currently comprises eight classes: *Anaerolineae*, *Ardenticatenia*, *Caldilineae*, *Chloroflexia*, *Dehalococcoidia*, *Ktedonobacteria*, *Thermoflexia*, and *Thermomicrobia*. Chlorophototrophic organisms occur in two classes: *Chloroflexia* and *Anaerolineae*. Most chlorophototrophs belong to the order *Chloroflexales*, which is further divided into two sub-orders: *Chloroflexineae* and *Roseiflexineae*. These two suborders include organisms colloquially called FAPs, filamentous anoxygenic phototrophic bacteria, which can often be differentiated by their color (*Chloroflexineae*: green; *Roseiflexineae*: reddish-brown) and by the presence (*Chloroflexineae*) or absence (*Roseiflexineae*) of chlorosomes. Because most do not require reduced sulfur compounds for growth, they were formerly called “green non-sulfur bacteria.” Members of the *Chloroflexales* grow facultatively as aerobic chemoheterotrophs in the dark and grow as anaerobic photoheterotrophs in the light. Some members can grow photoautotrophically and/or photomixotrophically under anoxic conditions in light. Green-colored FAPs occur in two families, *Chloroflexaceae* and

Oscillochloridaceae. Cell suspensions are usually greenish-brown in color under anoxic conditions because the cells produce chlorosomes that contain BChl *c* with an *in-vivo* absorption maximum at ~740 nm (Fig. 2(k) and (l)); BChl *a* is additionally present (and sometimes BChl *d*). Unlike GSB, FAPs have type-2 RCs and lack FMO. Instead, a membrane-associated LH1-like complex with absorption bands at 808 and 866 nm surrounds the RC and functionally replaces FMO. All described *Chloroflexaceae*, *Chloroflexus* spp. and "*Candidatus Chloranaerophilum corporosum*," are thermophilic, unbranched, multicellular filamentous bacteria. They inhabit freshwater hot springs and grow well at ~55°C, and most exhibit gliding motility and flexing. All characterized *Chloroflexus* spp. have the genetic potential to fix CO₂ by the 3-hydroxypropionate bi-cycle, a pathway exclusively found in *Chloroflexi*. Most strains grow mixotrophically, but autotrophic growth has been demonstrated for *Cfl. aurantiacus* strains OK-70-fl (DSM 636) (with H₂) and *Chloroflexus* sp. MS-G (with H₂S).

The family *Oscillochloridaceae* is a second family of green-colored FAPs, which mostly includes mesophilic filamentous, freshwater bacteria with gas vesicles and an outer sheath. Cultures of the type species, *Oscillochloris trichooides* DG-6^T, are green or yellow-green in color due to the presence of BChl *c*-containing chlorosomes and BChl *a*. In contrast to other FAPs, *O. trichooides* grows photolithoautotrophically by using the Calvin-Benson-Bassham cycle (reductive pentose-phosphate cycle).

A novel green FAP, provisionally named "*Candidatus Chloranaerofilum corporosum*," was recently found in a hot spring microbial mat in Yellowstone National Park. This novel FAP was first detected in metagenomic analyses of the orange-colored undermat and is a member of the suborder *Chloroflexineae*; however, it presently cannot be affiliated reliably with either of the two families of this suborder (<91% nucleotide identity). This FAP contains BChls *a* and *c* and grows at 52°C as long filaments of single cells, which have a relatively large diameter of ~2 µm and are separated by obvious septa. Suggesting the capacity for photoautotrophic or photomixotrophic growth, the partial genome contains genes encoding for enzymes of the 3-hydroxypropionate bi-cycle. However, autotrophic growth has not yet been tested, and the strain is currently grown photoheterotrophically.

Red FAPs of the genus *Roseiflexus* (family *Roseiflexaceae*) are the only described strains currently available (e.g., *Roseiflexus castenholzii*; other previously described strains (e.g., *Heliothrix oregonensis*) have been lost. Red FAPs are (moderately) thermophilic and have been found in slightly sulfidic (<0.5 mM sulfide) hot springs, where they form orange-, reddish- or pink-colored mats. Red FAPs synthesize BChl *a*, carotenoids, LH1, and type-2 RCs but lack BChl *c* and chlorosomes. *Roseiflexus* (*Rof.*) *castenholzii*, the only validly described species, was isolated from Nakabusa Hot Springs in Japan. It forms a distinct, dense reddish or pink layer underneath mats of *Cyanobacteria* and *Chloroflexus* spp. at temperatures of 45.5–68.5°C at pH 7.8–8.2. *Rof. castenholzii* grows photoheterotrophically under anoxic conditions in the light as well as chemotrophically under dark oxic conditions. Similar members of this genus have been observed or isolated from hot springs in Yellowstone National Park. Like *Rof. castenholzii*, the Yellowstone isolates contain BChl *a*, lack BChl *c* and chlorosomes, and grow photoheterotrophically or chemoheterotrophically under dark aerobic conditions. Although photoautotrophic growth has not been observed, the presence of genes encoding all enzymes of the 3-hydroxypropionate bi-cycle, as well as stable carbon isotopic compositions of FAP biomarkers, strongly suggest that photoautotrophic or photomixotrophic growth occurs *in situ*.

Red FAPs are no longer monophyletic because of the recent discovery of an uncultured organism that probably belongs to the class *Anaerolineae*. Metagenomic analyses of hot spring microbial mats from Yellowstone National Park initially suggested the existence of a chlorophototrophic member of the *Anaerolineae*. The metagenomic bin representing this organism contains *pufLM* genes encoding a type-2 RC as well as enzymes for the synthesis of BChl *a* but not BChl *c*. Very thin filaments (~0.2 µm in width) are observed in mat samples and enrichments with lengths of ~15–50 µm, which exhibit autofluorescence from BChl *a* but not BChl *c*. These filaments probably represent this novel phototroph, which has provisionally been named "*Candidatus Roseilinea gracile*." Interestingly, *Roseiflexus* sp. RS-1 as well as "*Ca. Roseilinea gracile*" contain rhodopsin genes with phylogenetic affiliation to light-driven, xanthorhodopsin-like H⁺ pumps, indicating the possible co-existence of retinal-based phototrophy and chlorophototrophy in these FAPs. Finally, a poorly described member of the red FAPs is the type-isolate of Eikelboom morphotype 1851, *Kouleothrix aurantiaca*. On the basis of its 16S rRNA gene sequence as well as the presence of genes for chlorophototrophy, *K. aurantiaca* appears to be a new member of the red FAPs.

Firmicutes: Heliobacteriaceae

Gest and Favinger described the first chlorophototrophic member of the phylum *Firmicutes* in 1983. The serendipitous discovery resulted from an error in preparing a standard growth medium, which resulted in the enrichment and eventual isolation of a brownish-green, nitrogen-fixing, spore-forming rod, *Heliobacterium chlorum* (Fig. 2(g)). Heliobacteria characteristically produce "homodimeric" type-1 RCs that contain BChl *g*, which is extremely sensitive to oxygen, and 8¹-OH-Chl *a*, which acts as the primary electron acceptor in RCs. Heliobacterial cells lack intracytoplasmic membranes and do not produce a light-harvesting antenna system other than PshX, which is associated with the RCs.

Neutrophilic heliobacteria are common in diverse soils and rice paddies, where they may form symbiotic relationships with the roots of rice plants. Alkaliphilic species are known as well. The model organism for the group, *Heliobacterium modesticaldum*, was isolated from a hot spring microbial mat in Iceland, and similar organisms have been isolated from alkaline siliceous hot springs in Yellowstone National Park, WY, USA. The family *Heliobacteriaceae* currently includes only four genera and eleven species. Heliobacteria resemble clostridia and have a Gram-positive cell wall comprised of a thick layer of peptidoglycan but no outer membrane; they form heat-resistant endospores that remain viable during periods of environmental stress. Heliobacteria use electrons derived from organic compounds and light energy to produce strongly reducing ferredoxins that are used for nitrogen fixation. Consistent

with the photoheterotrophic lifestyle of all known members, the 3.08-Mbp genome of *H. modesticaldum* encodes enzymes of the incomplete rTCA cycle, but no complete C_i fixation pathway is present.

Acidobacteria: Chloracidobacterium thermophilum

Chloracidobacterium (*Cab.*) *thermophilum*, the first and currently the only chlorophototrophic member of the phylum *Acidobacteria*, was initially detected by metagenomic analyses of microbial mat communities associated with slightly alkaline, siliceous hot springs in Yellowstone National Park, WY, USA (Fig. 2(h)). Following the identification of a gene encoding an unusual core subunit of a homodimeric type-1 RC, a bacterial artificial chromosome fragment of the genome was identified that encoded an rRNA operon and the *pscA-pscB-fmoA* operon. Analyses of these sequences confirmed that the rRNA operon belonged to a member of the phylum *Acidobacteria*. An enrichment culture that contained *Cab. thermophilum* and two aerobic heterotrophs was initially obtained. Studies with this enrichment showed that *Cab. thermophilum* is an obligate chlorophototroph and allowed initial characterization of the organism, its photosynthetic apparatus, and its genome. *Cab. thermophilum* has two chromosomes of 2.68 and 1.01 Mbp. Based upon knowledge gained from the genome sequence and a metatranscriptomic analysis, classical microbiological and physiological methods led to the isolation of an axenic culture and a formal description of this novel organism.

Cab. thermophilum is the first oxygen-requiring, anoxygenic BChl-containing bacterium that contains a homodimeric, type-1 RC, chlorosomes, and the FMO protein, which previously were only known to occur in strictly anaerobic members of the GSB ("*Ca. Thermochlorobacter aerophilum*" is similar). BChl *c* and keto-carotenoids are the major light-harvesting pigments in the chlorosomes, whereas BChl *a*, Chl *a* and Zn-BChl *a'*, are found in the type-1 RCs. As in the RCs of GSB, Chl *a* apparently acts as the primary electron acceptor, which suggests that Zn-BChl *a'* is possibly the primary donor of this RC. The *Cab. thermophilum* genome lacks key enzymes of all known carbon fixation pathways, yet bicarbonate is essential for growth; it presumably is employed in essential anaplerotic reactions, possibly the synthesis of 2-oxoglutarate from succinyl-CoA. As was inferred from the genome sequence and established through nutritional and biochemical studies, *Cab. thermophilum* requires all three branched-chain amino acids (which it can degrade but cannot synthesize), lysine, vitamin B₁₂, and a reduced sulfur source. *Cab. thermophilum* is unable to grow under anoxic conditions; it requires oxygen for essential anabolic reactions (e.g., for BChl and carotenoid biosynthesis as well as the synthesis of tyrosine from phenylalanine).

Survey studies by enrichment and cultivation, by sequencing the 16S rRNA gene, and by metagenomics show that *Cab. thermophilum* is found at temperatures from ~40–68°C at slightly alkaline pH around the world. Phylogenetic analyses of 16S rRNA genes from different locations strongly suggest that additional species may occur in the genus *Chloracidobacterium*. Physiological experiments with axenic strains of *Cab. thermophilum* from Mushroom Spring (Yellowstone National Park, WY, USA), as well as a 16S rRNA survey of another hot spring mat community, indicate that ecotypes with different adaptations to temperature and perhaps other parameters occur.

Gemmatimonadetes: Gemmatimonas Phototrophica

Using a high-throughput fluorescence screening approach, a novel chlorophototroph, *Gemmatimonas phototrophica*, from the bacterial phylum *Gemmatimonadetes* was initially isolated from a freshwater lake in the Gobi Desert in North China in 2011. This discovery extended the number of bacterial phyla containing chlorophototrophs from six to seven. *G. phototrophica* is an aerobic, anoxygenic photoheterotroph; it is a slow-growing, red-colored, mesophilic, oligotroph that is closely related to the aerobic chemoheterotroph, *Gemmatimonas aurantiaca* (Fig. 2(q)). *G. phototrophica* produces BChl *a* and fully functional type-2 RCs and LH1, but light energy is only used as an auxiliary energy source that supplements the chemoheterotrophic lifestyle of this organism. The 4.7-Mbp genome of *G. phototrophica* includes a 42.3-kb gene cluster encoding all of the genes required for chlorophototrophy. Phylogenetic analysis indicates that this gene cluster was obtained by horizontal gene transfer from a proteobacterium, the first clear evidence for transfer of chlorophototrophy between such distantly related taxa. Metagenomic analyses indicate that organisms related to *G. phototrophica* occur in diverse freshwater and terrestrial environments, where they can account for up to ~12% of the chlorophototrophic community.

Concluding Remarks

Retinalphototrophy is a relatively simple mechanism that allows microorganisms to supplement their ATP production when nutrient resources are limiting. If an organism can synthesize β -carotene, only two additional gene products are required, and thus horizontal gene transfer has broadly spread this capability among diverse bacteria and archaea. In contrast, chlorophototrophy can produce both reducing power and/or proton motive force that can be used to drive C_i fixation. Although more complex, some bacteria (e.g., AAPB) use chlorophototrophy merely as a mechanism to supplement ATP production under unfavorable growth conditions. Chlorophototrophic bacteria, predominantly cyanobacteria, are responsible for about half of the primary productivity on Earth. Thus, chlorophototrophs are foundational members of diverse microbial communities in both oxic and anoxic environments, and they play extremely important roles in globally important processes relating to major geochemical cycles, including carbon, nitrogen, and sulfur cycling. Many new chlorophototrophs have been identified and characterized through genomics and metagenomics in the past decade, and it is likely that more discoveries remain to be made.

Glossary

Coevolution Interdependent evolution between organisms.

Distance tree Phylogeny created by converting alignment data into numerical distances and successively grouping taxa based on the smallest distances.

Gammaproteobacteria The gamma subclass of Gram-negative bacteria within the phylum Proteobacteria.

Homologue Gene sharing a common ancestry (see also **orthologue** and **paralogue**).

Horizontal gene transfer (HGT) Nonancestral movement of genes between organisms.

Housekeeping gene A gene whose product has a role in maintaining cellular function.

Likelihood tree Phylogeny based on statistical evaluation of alignment data and substitution matrix.

Long branch attraction (LBA) The erroneous clustering of fast evolving sequences due to shared character states that may not be the result of descent.

Orthologue Gene inherited vertically during speciation.

Paralogue A duplicated gene copy.

Substitution matrix A model of molecular sequence evolution that estimates the transition frequency of residues from one state to another.

Supermatrix Concatenation and alignment of multiple genes.

Supertree Consensus phylogeny of multiple independent gene genealogies.

Xenologue A gene inherited via horizontal gene transfer.

Abbreviations

Fn3	Fibronectin type III domain
HGT	Horizontal gene transfer
LBA	Long branch attraction
MCMC	Markov Chain Monte Carlo
ML	Maximum likelihood
NJ	Neighbor-joining
PP	Posterior probability
UPGMA	Unweighted pair group method with arithmetic mean

Defining Statement

This article examines the recent use of phylogenetic methods to infer relationships among bacteria, comparing results from single-gene and whole-genome analyses, and also from alignment-dependent and alignment-free approaches. The application of phylogenetic approaches for examining coevolution and horizontal gene transfer (HGT), and for establishing levels of diversification within protein superfamilies, are also examined.

Introduction

The ultimate goal of phylogenetics is to establish the evolutionary relatedness and relationships among genes, traits, or organisms. And although life has a single origin and only one true evolutionary history, the task of reconstructing this history can range from facile to formidable depending on the particular taxa or characters in question. Difficulties arise with phylogenetic reconstruction due to the fact that virtually all inferences about evolution and relationships are based on the study of contemporary organisms. It is rarely possible to fill in gaps – to verify how the record of life actually unfolded – by including archaic or extinct lineages.

[☆]*Change History:* July 2015. J He reviewed the article and made minor editorial changes.

This article is an update of J. Stavrinos, H. Ochman, *Phylogenetic Methods*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 247–260.

These problems are magnified in bacteria because they possess few visible traits and almost no fossil record. Moreover, bacteria are ancient and have diversified over billions of years and are subject to processes of horizontal gene transfer (HGT), which can potentially introduce any trait in any lineage and obscure traditional Darwinian patterns of descent, thereby making their history even more difficult to trace.

During the first hundred years of microbiology, bacteria were classified, distinguished, and grouped largely by their habitats, growth characteristics, biochemical attributes, and virulence potential. But during the latter half of the twentieth century, there was a pronounced shift toward the use of molecular genetic information, as gained through the analysis of protein and nucleic acid sequences. This provided three immediate advantages. First, comparative analyses became centered on universally distributed characters, which eliminated the situation whereby lineages are classed together due to their lack of specific defining feature(s). Second, in-depth knowledge of the physical mechanisms by which informational macromolecules can change has led to the development of robust models of sequence evolution. Third, the use of molecular sequences increased substantially the number of discrete characters by which microorganisms could be compared in that each nucleotide or amino acid residue can potentially serve as an informative trait.

Although the use of molecular sequences has undoubtedly revolutionized the study of microbial systematics and evolution, all inferences rely on two factors: the particular character(s) used for phylogenetic reconstruction and the algorithms used to infer relationships. As with phenotypic traits, molecular sequences are subject to character convergence as a result of chance events, natural selection, or horizontal transfer. Moreover, the vast amount of information obtained from a single sequence has often confined analyses to a single region of the genome, which may not be representative of the organism as a whole. Finally, phylogenetic methods have very distinct sets of underlying assumptions. Such problems stress the need to examine multiple genes and to infer statistically robust phylogenetic trees in order to recognize and understand any inconsistencies in the data.

In this article, we explain and examine the procedures by which microbial phylogenies have been and are being produced. We concentrate on the advantages and limitations of the various phylogenetic methods, and on the particular relationships evoked from varied types of genetic data, including full genome sequences, considering the phylogeny of Gammaproteobacteria. Due to the long-standing interest in its host-associated members, the Gammaproteobacteria have been the subject of concentrated genome sequencing efforts, resulting in a large amount of sequence information that makes this group particularly suitable for testing and evaluating methods of phylogenetic reconstruction.

Phylogenetic Analysis of Molecular Sequences

The use of molecular sequence data to infer relationships has been central to our understanding of evolution and evolutionary processes. Changes at the molecular level have been used to establish the phylogeny of many types of organisms. For microbes, in particular, where classic phenotypic markers are often ineffective or impractical for grouping bacterial isolates, molecular phylogenetic approaches have been revolutionary. Here, we outline the approaches involved in sequence-based phylogenetic reconstruction, covering the manner in which sequences are aligned, followed by the methods for translating alignments into a phylogeny.

Sequence Alignments

The prerequisite for producing an organismal phylogeny based on molecular sequences is a highly refined alignment of orthologous (vertically inherited) sequences that best approximates their true molecular evolution. Alignments can be generated with a variety of algorithms, most of which employ some form of substitution matrix to position homologous nucleotides or amino acid residues so as to maximize the number of identical or similar residues at a given site (column). The specific values in a substitution matrix provide the algorithm with the rate at which one character (nucleotide or amino acid) changes to an alternate state. Clustal, presently the most popular alignment software, uses the IUB and ClustalW1.6 matrices for DNA alignments, and the PAM, BLOSUM, and Gonnet matrices for amino acid alignments. To facilitate the alignment process, these algorithms can also introduce gaps at a frequency dictated by the particular gap opening and gap extension penalties, thereby reflecting biologically relevant insertions/deletions (indels) within the sequence. The introduction of gaps within a coding sequence, however, may sometimes be undesirable, as this is likely to infer insertions and deletions that may not be accurate representations of the actual molecular evolution of the sequences. This is particularly true of functional protein-coding sequences, in which the introduction of alignment gaps may result in nonsensical frameshifts.

When a sequence dataset is put into a residue-based alignment program, such as Clustal, the algorithm begins by creating a pairwise alignment of all sequences independently. The algorithm then calculates all distances between sequence pairs, creating a distance matrix that is subsequently translated into a guide tree (dendrogram). As its name suggests, this tree serves as a guide for beginning the multiple sequence alignment, with the most similar sequences being added first, followed by the progressive addition of more divergent sequences. This simple and relatively effective type of pairwise progressive sequence alignment approach has been used extensively in numerous phylogenetic studies, but is less effective for particular datasets. This has prompted the development of more improved alignment algorithms, such as MUSCLE, t-Coffee, POA, DIALIGN, SAGA, and MAFFT, which are efficient and accurate in recovering optimal alignments from various datasets, as established by comparison to BALiBASE (a database of manually refined reference alignments). Not all of these algorithms, however, are procedurally equivalent. Some, such as DIALIGN, utilize a segment-to-segment comparison whereby regions of sequence similarity are used as anchors around which the entire alignment is built, whereas others, such as MUSCLE, t-Coffee, and MAFFT, perform a series of progressive alignments that refine and optimize

during each iteration to ensure significantly higher alignment accuracy. The refined, progressive alignment offered by these approaches is essential for the accurate reconstruction of phylogenetic relationships.

Regardless of the program or algorithm used to generate the multiple sequence alignment, each alignment must be evaluated prior to its use for phylogenetic reconstruction. Sequence variation across an alignment may be heterogeneous, resulting in conserved regions being interspersed among highly variable regions. Since the alignment of hypervariable regions is often questionable, these portions are best masked or eliminated. This is particularly important because even small changes in the alignment will introduce noise that can potentially obscure the true phylogeny. As mentioned previously, it is also often necessary to optimize the alignment by adjusting gap opening and extension parameters and, in extreme cases, refining the alignment manually.

Phylogenetic Reconstruction

Once a reliable alignment is generated, a variety of tree-building methods can be utilized to transform the alignment data into a phylogenetic tree. These tree-building methods are categorized broadly into distance-based, parsimony, and likelihood approaches, each of which will be considered below (Table 1).

Distance trees

Distance-based approaches cluster representative taxa based on the number of nucleotide or amino acid substitutions between sequences. One of the original and simplest distance-based methods, developed for the generation of phenetic cladograms, was UPGMA (Unweighted Pair Group Method with Arithmetic Mean). UPGMA utilizes a successive clustering approach, whereby a matrix of all pairwise sequence similarities is generated, and the two taxa with the smallest distance are clustered first. The distance matrix is recalculated, considering the already clustered taxa as one, and the taxon with the next smallest distance is added to the tree. This is repeated until all taxa have been added, and a final phylogeny constructed. Because of this simplistic interpretation of the distance matrix and assumption of a constant evolutionary rate (molecular clock) for all sequences, UPGMA was prone to constructing unsupported phylograms. The Neighbor-Joining (NJ) method, which had a similar approach to taxonomic grouping as UPGMA, clusters closest sequences (neighbors) first and then recalculates the distances between neighbor pairs. Because of this, NJ does not suffer from the same limitations as UPGMA and has become the preferred distance-based method for phylogenetic reconstruction.

Distance-based phylogenetic reconstruction requires the calculation of the number of changes that have occurred in a given sequence; however, determining the exact number of substitutions between any pair of sequences, particularly highly diverged sequences, is virtually impossible. For example, it is often not clear whether the presence of different nucleotides at an aligned site

Table 1 Sorting through the phylogenetic methods applied to microbes

<i>Approach</i>	<i>Advantages</i>	<i>Disadvantages</i>
Single-gene	● Requires sequence information from only one locus	● Evolutionary history of individual loci may not be representative of entire genome/organism
UPGMA	● Rapid ● Highest accuracy when molecular rates are constant along lineages	● Assumes molecular clock ● Simple interpretation of distance matrix ● Always creates rooted trees ● Sequence information reduced to distances
Neighbor-joining	● Rapid ● Can be used with large datasets ● Produces reliable phylogenies with most datasets	● Sequence information reduced to distances ● Strongly influenced by substitution model ● Always produces only one possible tree
Maximum likelihood	● Produces robust phylogenies ● Dataset can utilize bootstrap	● Computationally intensive ● Not suitable for large datasets
Bayesian	● Rapid ● Suitable for larger datasets	● May be prone to creating unsupported phylogenies ● Does not always yield fully resolved phylogenies ● Uses more permissive posterior probability for topological support
Whole-genome	● Not as sensitive to evolutionary forces affecting individual genes	● Amount of phylogenetic signal unknown
Genome content	● Can be used to analyze many genomes	● Not suitable for reduced genomes ● Requires normalization to account for genome size variation ● Relies on accurate inference of homologues and/or orthologues ● No models available for evolution of the genetic repertoire
Gene order	● Can be used to analyze many genomes	● Computationally complex so scaling to multiple genomes difficult ● Genomic alignment difficult if additions, deletions, and inversions prevalent
Rearrangement/breakpoint distance	● Can be used to analyze many genomes	● Computationally complex so scaling to multiple genomes difficult
Alignment-free	● Rapid ● Simple to execute	● No models available for genome evolutionary dynamics ● May be subject to character convergence

occurred by a single or by multiple substitutions. Likewise, two sequences that are identical at a given position may not necessarily indicate the absence of a substitution, since it is possible that the sequence conservation at that site is due to an unobserved change followed by a reversion back to its original state.

This concept, known as ‘multiple hits’, requires correction during the estimation of pairwise distances. Numerous substitution models have been created to approximate multiple changes at the same site and are often incorporated into the calculation of pairwise distance/divergence between sequences. Substitution models for DNA may be simple, such as the Jukes–Cantor method, which assumes that any nucleotide has an equal probability of changing to any other (a single substitution rate for all nucleotides), or more complex, such as the General Time Reversible model, which assumes different rates depending on the particular nucleotide substitution. Similarly, substitution models for proteins, as discussed above, include the PAM, BLOSUM, and the more recently derived Jones–Taylor–Thornton matrices. The choice of substitution model can have significant impact on phylogenetic reconstruction, particularly when the true tree contains long branches separated by short internal branches. Several applications, such as MODEL TEST, have been developed to ascertain the best substitution model for a given set of sequences.

Likelihood trees

The application of likelihood methods to phylogenetic reconstruction has become increasingly popular over the last decade, due largely to their somewhat greater accuracy and consistency in recovering a correct phylogeny, and due to the significant increases in computational capacity and speed. Maximum likelihood (ML) and Bayesian approaches offer two distinct, but related, probabilistic approaches to determine the best phylogeny. ML approaches attempt to identify the tree topology that has the highest probability given the sequence data provided. This requires calculation of the log likelihoods for all possible tree topologies for a given dataset, with the tree having the highest likelihood being favored. Because all tree topologies must be sampled and evaluated with this approach, ML is computationally intensive and unsuitable for very large datasets.

The Bayesian approach to phylogenetic reconstruction is considered by many to be an ideal alternative to the ML approach. This method relies on Bayes’ theorem, which takes into account the sequence data provided (likelihood) and the assumptions that can be made about the data (priors) to calculate a posterior probability (PP) for a given topology. Bayesian analyses utilize an algorithm known as Markov Chain Monte Carlo (MCMC), which explores and samples ‘tree space’ (the entire set of possible trees for a given dataset) and estimates the PP of each. The MCMC algorithm begins at multiple random locations in tree space, with each point (or chain) beginning to sample trees randomly. As each chain explores tree space, any tree sampled that has a higher PP than the previous tree serves as the starting point for the next sampling iteration, allowing the algorithm to sample those topologies with increasingly larger PP. Millions or hundreds of millions of generations are generally run with sampling frequency being at the discretion of the user. Ideally, all chains should converge on the same PP distribution, indicating that the trees with the highest PP distribution have been sampled; however, because tree space has many local maxima and minima, chains sometime become fixed at a local peak and incapable of crossing a valley toward a higher posterior distribution. A variant of the MCMC algorithm, called Metropolis-coupled MCMC (or MC³), was developed to circumvent this problem.

Unlike distance-based approaches, the Bayesian approach does not produce a single tree; rather, it samples a series of probable tree topologies based on the dataset and priors. The entire tree set is first refined to eliminate the initially sampled suboptimal tree topologies and a consensus made of the remaining refined dataset. Because posterior probabilities have already been calculated during sampling, these are used to determine confidence values at each node on the tree, eliminating the need further access the statistical support of the topology by procedures such as the bootstrap or jackknife (see below).

Parsimony trees

Parsimony methods for phylogenetic reconstruction are premised on favoring the evolutionary path with the fewest number of changes. Unlike distance-based methods, parsimony relies on character-based inference of phylogenies, utilizing the sequence data in its original state rather than converting it to distances. One of the more popular parsimony methods is Maximum Parsimony, a tree-constructing approach that calculates the evolutionary steps for all likely tree topologies and presents the tree with the fewest evolutionary steps. Often, there are multiple, equally parsimonious trees, some having drastically different topologies than others. Much like the Bayesian approach, a consensus phylogeny may be built on this tree set, thereby combining all topologies into a single approximated tree topology.

Interpreting Phylogenetic Trees

There are several issues to consider when evaluating a phylogenetic tree. Of utmost importance is assessing the support and validity of the recovered topology. The support for the relative position of each taxon in a distance-based or parsimony-inferred phylogenetic tree is often evaluated with the parametric bootstrap or jackknife. The bootstrap is a resampling with replacement technique that effectively creates multiple datasets from the original sequence alignment and places data points in the process. Portions of the topology that are consistently recovered are given higher bootstrap values than those that vary between replicates. This approach is similar to that employed by the jackknife, except that instead of replacing sites, the jackknife approach deletes sites, that is, resamples without complete replacement. For Bayesian phylogenies, PP is used specifically as an assessment of confidence; however, this has been shown to be less conservative than the bootstrap or jackknife. While a bootstrap >70% is typically considered reasonable support for a node, a PP >95% is considered equivalent support in a Bayesian phylogeny. It should be noted that when attempting to evaluate the validity of a phylogeny, confidence values (bootstrap, jackknife, and PP) provide some

benchmark as to whether the sequence data support the observed branching pattern but need not corroborate the relationships within the tree.

The addition of new taxa, changes in the specific parameters used for generating the tree, or even the use of an alternate tree-building method, can result in a dramatically different phylogeny with equally high confidence values. Similarly, low support values do not necessarily suggest an incorrect topology, but are instead indicative of either inadequate or extremely high sequence variation. In the case of insufficient sequence variation, nucleotide sequences can provide substantially more informative variation over protein sequences, and in some cases, additional representative sequences are required. In cases of extremely high sequence variation, refining the sequence alignment and removing hypervariable regions can significantly enhance phylogenetic signal and increase bootstrap support. Alternatively, a slower evolving locus may have to be substituted to better resolve specific relationships. Irrespective of the circumstance, a disproportionate emphasis should not be placed on confidence values when attempting to validate the branching order in a recovered phylogeny.

Another issue that often emerges during phylogenetic reconstruction is the concept of long branch attraction (LBA). LBA is an artifact whereby two sequences are grouped together in a phylogenetic tree as a consequence of having a greater number of substitutions relative to others. Higher sequence variability increases the chance of sharing common states by chance, causing many tree-building approaches to misinterpret this as higher relatedness. Parsimony and distance-based methods are prone to LBA, while ML and Bayesian are, in theory, immune to such artifacts; however, there is some evidence that this can occur in these latter two methods under certain circumstances.

Most phylogenetic approaches assume a strictly bifurcating topology; however, this assumption may be particularly limiting when considering microorganisms, which may be prone to exchanging genetic material. Recombination (and HGT) may obscure the pattern of organismal descent and require alternative methods for reconstructing and testing phylogenetic trees. Split decomposition methods do not impose a strictly bifurcating topology; rather, trees may be network-like, with reticulations in the network reflecting recombination between taxa. Genes having undergone such horizontal exchange are generally not considered reliable for accurate phylogenetic reconstruction. Thus, when attempting to establish bacterial relationships, the choice of locus becomes critical to accurately recovering the correct evolutionary history for a given set of isolates.

The use of the 16S rDNA sequences has become the standard for bacterial identification and phylogenetic reconstruction due to its reduced likelihood for HGT, relatively slow rate of change, and predisposition to concerted evolution among the 16S operons within a single genome. But on account of the latter two characteristics, 16S sequences also pose severe limitations in resolving relationships between closely related lineages. To increase phylogenetic resolution, some studies have turned to bacterial 'house-keeping' genes for assessing bacterial relationships. By being both conserved among diverse bacterial lineages and under purifying selection (but containing rapidly evolving synonymous sites), these genes can provide the basis for determining relationships at several taxonomic levels. Protein coding genes are not immune to the effects of HGT, making explicit tests of recombination necessary for each locus prior to its inclusion in phylogenetic analyses.

In some cases, the phylogenetic signal associated with recombination/HGT within one locus can be diluted by the concatenation of multiple genes that are distributed around the bacterial chromosome. This concatenation approach is increasingly popular and has provided fairly robust species trees for a variety of different bacterial groups; however, there is substantial debate as to whether these genealogies reflect true species trees given the occurrence of HGT. Thus, with an increasing number of whole genome sequences becoming available, bacterial taxonomy has turned to nonsequence-based whole genome phylogenies, whereby genome composition, content, synteny, and other characteristics are harnessed to infer relationships in an attempt to circumvent several of the confounding factors that might otherwise affect single-gene trees.

Toward Resolving the Relationships Among the Gammaproteobacteria

The availability of numerous methods for establishing bacterial relationships has prompted intense comparative analyses that test the effectiveness, reliability, and consistency of these diverse phylogenetic approaches. The Gammaproteobacteria, comprising many sampled and well-characterized medically, agriculturally, and environmentally relevant bacteria, have been the subject of intense sequencing efforts and have served as the focus of such analyses.

In 2003 Lerat and colleagues attempted to resolve the relationships among gammaproteobacterial species by identifying the set of single copy (core) genes that could be used for phylogenetic inference. Orthologous sequences were extracted from each of 13 genomes (*Buchnera aphidicola* APS, *Escherichia coli* K12, *Haemophilus influenzae* RdKW20, *Pasteurella multocida* Pm70, *Pseudomonas aeruginosa* PAO1, *Salmonella enterica* sv. typhimurium LT2, *Vibrio cholerae* O1 bv. eltor str. N16961, *Wigglesworthia brevipalpis*, *Xanthomonas axonopodis* pv. citri str. 306, *Xanthomonas campestris* pv. campestris str. ATCC33913, *Yersinia pestis* CO92, and *Y. pestis* KIM) and the evolutionary history of each single-copy orthologue was examined. All except two of the 205 genealogies were found to be congruent, with the two exceptions exhibiting a single event of HGT. Compared to what is currently known about the relationships among these taxa based on 16S (Figure 1(a)), the resulting phylogeny was largely congruent (Figure 1(b)), illustrating that although HGT might complicate phylogenetic inferences, the selection of appropriate loci can help circumvent such problems. Despite the strong statistical support for this tree, Susko and colleagues, in 2006, suggested that perhaps 10% of the core gene genealogies had conflicting evolutionary histories, which could be indicative HGT, leading to their suggestion that the Gammaproteobacteria would be best represented as a network, rather than a traditional bifurcating tree.

The phylogeny of these 13 gammaproteobacterial genomes, as deduced by Lerat and colleagues currently serve as the benchmark for comparing evolutionary relationships deduced by other approaches that based on either different methods of phylogenetic

Figure 1 (a) Neighbor-Joining (NJ) phylogeny of 13 species from the Gamma subdivision of the Proteobacteria based on 16S rDNA. Reproduced from Luo YQ, Fu C, Zhang DY, and Lin K (2006) Overlapping genes as rare genomic markers: The phylogeny of [Gamma]-Proteobacteria as a case study. *Trends in Genetics* 22: 593–596. (b) NJ phylogeny of 13 species from the Gamma subdivision of the Proteobacteria generated by Lerat and colleagues, in 2003, using a 203-gene concatenated dataset. Reproduced from Lerat E, Daubin V, and Moran NA (2003) From gene trees to organismal phylogeny in prokaryotes: The case of the gamma-proteobacteria. *PLoS Biology* 1: 101–109. (c) Phylogeny recovered from supertree and supermatrix approaches of the Gammaproteobacteria. Reproduced from Comas I, Moya A, and Gonzalez-Candela F (2007) From phylogenetics to phylogenomics: The evolutionary relationships of insect endosymbiotic gamma-proteobacteria as a test case. *Systematic Biology* 56: 1–16.

Figure 1—Cont'd (f) Phylogenies of the Grammaproteobacteria using breakpoint distance (left), and common/conserved intervals (right), which differ in the position of the opportunistic pathogen *Pseudomonas aeruginosa*. In both phylogenies, the endosymbionts *Buchnera aphidicola* and *Wigglesworthia glossinidia* are not resolved as a monophyletic group as in the phylogeny of Lerat and colleagues (2003), but do cluster within the Enterobacteriaceae. Reproduced from Blin et al. (2005) In: *Comparative Genomics*. RECOMB 2005 International Workshop, RCG 2005. Lecture Notes in Bioinformatics, vol. 3678, pp. 11–20. (g) Phylogenetic relationships among 13 species from the Gammaproteobacteria using whole-genome gene order data. Taxa not included in original study by Lerat and colleagues are in gray typeface.

reconstruction or alternate molecular characters (see below). For example, a recent study by Comas and colleagues, in 2007, examined 21 genomes, including the original 13 analyzed by Lerat and colleagues, and identified 579 orthologous genes that could be used for establishing phylogenetic relationships and creating a species tree. Two distinct approaches were used to evaluate phylogenetic signal: supermatrix (gene concatenation) and supertree (consensus of multiple tree topologies). Both approaches recovered a single supported topology, which was congruent to the phylogeny of Lerat and colleagues (see Figure 1(c)).

Whole-Genome and Sequence Alignment-Free Approaches

Up to this point, this article has been devoted to evolutionary inferences based on the alignment of the primary sequences of DNA or proteins. The availability of complete genomes has engendered a pronounced increase both in the number of sequences that can

be compared across taxa and in the resolution of phylogenetic trees. Analyses of the complete set of genes in genomes are usually thought to be more resistant to evolutionary processes or statistical artifacts that might affect phylogenetic reconstructions based on individual genes (Table 1).

In addition to the accuracy that might be gained through the incorporation of numerous genes, the availability of full genomes has also led to the development numerous methods that exploit characters other than nucleotide or amino acid substitutions to establish the relationships among organisms. But before describing these procedures, it should be noted that unlike the sequence alignment-based methods, there is rarely a robust, *a priori* model describing the evolution of the genomic characters on which these phylogenies are founded. Therefore, the results of such analyses are often compared to established gene genealogies before they are presumed to represent a true organismal phylogeny, and any similarities or incongruities help model the evolutionary dynamics of the particular genomic trait.

Several features can provide measures of similarity among genomes, which can then be transformed into a tree using a clustering algorithm, such as the NJ method or UPGMA. The use of whole-genome information to infer phylogenetic relationships (sometimes referred to as 'phylogenomics') has been the subject of two excellent and comprehensive reviews by Snel et al., 2005 and Delsuc et al., 2005. Below, we discuss briefly several of the whole-genome and the sequence alignment-free methods cited in these reviews, particularly those that address relationships among members of the Gammaproteobacteria, and then turn our attention to some recently developed procedures in this area.

Genome Content

Because full genome sequences provide the complete set of encoded genes (as well as knowledge of all genes that are absent), the earliest whole-genome approaches for inferring relationships were based on the proportion of shared genes among organisms. There are numerous mechanisms by which bacterial genomes can gain and lose genes; however, the rates and progression of such changes are not known and may therefore be highly variable across organisms. And as a metric, the fraction of genes by two genomes need not be reciprocal due to differences in genome size. As expected, larger genomes typically have higher numbers of genes and/or gene families in common, requiring either normalization of the similarity estimates by genome size or exclusion of microbes with highly reduced genomes.

Naturally, the observed similarity in genome repertoires will also be influenced by how shared genes are identified, and there is no single best method that can be applied to all genomes and all comparisons. Two basic approaches used include the 'homologue' method, which examines the taxonomic distribution of gene families or the representation of genomes in COGs, and the 'orthologue' method, which searches for the occurrence of 'true' orthologues, usually defined as sequences that are reciprocally the best matches in a pair of genomes. The latter is probably best applied to rather closely related organisms, since orthologues can be more reliably recognized.

Gene Order

The genes in a genome are arranged physically in an order that can be modified by additions, deletions, inversions, and translocations. Genetic maps revealed that despite differences in the particular set of genes harbored by an organism, overall gene order was highly conserved among related but divergent bacteria (e.g., *E. coli* and *S. enterica*); however, the earliest comparisons of fully sequenced genomes detected several local areas of synteny but little long-range conservation in gene order among species. Taken together, this suggests that gene arrangement contains some phylogenetic signal and could therefore be a useful feature for determining the evolutionary relationships among organisms. As additional genomes appeared, it became apparent that the degree of conservation of gene order reflected the evolutionary distance between organisms, indicating that genomes diverge principally by inversions that are symmetric with respect to the replication origin and terminus.

Due to the potentially large differences among genomes, early comparisons quantified gene order similarity by measuring the degree to which each pair of adjacent genes were retained as neighbors in another genome, a metric that auspiciously eliminated the need to initially align the corresponding genomes. Using this approach, gene order has usually been found to evolve more quickly than genome contents, which is perhaps not surprising given that changes to gene content (additions and deletions) and gene rearrangements (inversions and translocations) will both contribute to the disruption of gene adjacencies.

Kunisawa, in 2001, devised a method for reconstructing the relationships among organisms based on the physical order of conserved genes. In this method, the genome is scanned for pairs or clusters genes whose arrangements or orientations vary, and are phylogenetically informative across species. Genomes are grouped according to their shared gene arrangements with the changes in a particular gene order mapped parsimoniously to demarcate particular nodes along a phylogeny, and when applied to members of the several bacterial groups, the resulting topologies were consistent with the traditional sequence-based classifications. This method is similar in concept to analyses that use rare genomic changes as phylogenetically informative markers to denote evolutionary relatedness. Behind this approach is the notion that certain genetic events occur so infrequently that they are not subject to convergence or reversion and that organisms or genomes that possess the rare character share a more recent common ancestor than those that do not. Various types of genomic characters, including gene fissions or fusions, and the occurrence of specific insertions or deletions, have been used to define nodes in evolutionary trees, and whereas this approach is not based strictly on gene order, it relies on the presence or physical arrangement of particular genes or features within a genome.

A 2006 study by Luo and colleagues used the genome-wide occurrence of overlapping genes (i.e., adjacent genes whose coding regions overlap) as a way to determine the relationships among the Gammaproteobacteria. Because the dissociation of overlapping genes would probably have consequences on gene function, gene overlaps, once formed, are likely to be retained in that state in all descendent genomes containing those genes. Based on the presence of orthologous overlapping genes in 13 sequenced Gammaproteobacteria, this study computed the pairwise distance between genomes and reconstructed UPGMA and NJ phylogenies (Figure 1(d)) that differed from the canonical topology only in the placement of the two endosymbionts, *W. brevipalpis* and *B. aphidicola*. These insect endosymbionts have highly reduced genomes and therefore very few common gene pairs, making them less likely to be paired in analyses that are dependent on genome size and gene repertoires.

Rearrangement Distances and Gene Order (Breakpoint) Phylogenies

Although the phylogenies discussed in the previous section rely on the arrangement of genes or other characters within genomes to infer their similarity or relatedness, a complete genome sequence contains a substantial amount of information in addition to the sequence and occurrence of its constituent elements. Differences in gene order, expressed in terms of rearrangement distance – that is, the minimal number of events needed to transform one gene order into the other – reflect the evolutionary divergence between two genomes and can serve as a source of phylogenetic information. Unfortunately, phylogenetic methods based on gene order are computationally intensive and were previously restricted to the analysis of eukaryotic organelles, which have small and relatively constant gene sets. There have been two attempts to use complete genome sequences for reconstructing a gene order phylogeny for a bacterial genome. In 2005, Belda and colleagues circumvented the computational problems posed by variation in gene content (as resulting from duplications, deletions, and HGT), by extracting a common set of ~250 orthologous genes from each of 30 sequenced Gammaproteobacteria. By reducing each of the analyzed genomes to a small set of common genes, the calculation of rearrangement distances between all pairs of organisms becomes computationally equivalent regardless of their actual genome sizes. Similarly in 2005 Blin and colleagues performed a genome-wide breakpoint analysis of 12 Gammaproteobacteria, but instead considered all genes common to a given pair of genomes when computing their rearrangement distance. The phylogenies presented by both studies (Figure 1(e) and 1(f)) were topologically congruent to that of Lerat and colleagues.

Since the Gammaproteobacteria contain thousands of gene families, we have recently implemented a method that reconstructs a phylogeny based on complete gene order information of the entire complement of genes in fully sequenced genomes. This work made use of all ~3400 informative gene families (i.e., those present in more than two taxa) contained within 13 genomes and calculated the rearrangement distance between genomes by finding the most parsimonious sequence of three types of events – inversions, deletions, and insertions – that will transform the gene order of one genome into the other. The gene order tree derived computed from a normalized distance matrix by the NJ method differs from the sequence-based phylogeny in the placement of the clade containing *P. multocida*–*H. influenzae* (Figure 1(g)). This discrepancy matches that observed by Belda and colleagues and is consistently supported by jackknife resampling, which suggests that the source of the difference between the gene order and gene sequence phylogenies is biological, rather than methodological, and reflects distinctive patterns of genomic evolution in the affected lineages. Although all of the gene order trees are globally similar to the reference phylogeny, only in the present analysis are the two symbionts, *W. brevipalpis* and *B. aphidicola* grouped into a single clade.

Alignment-Free Methods

There have been several attempts to group bacteria and infer phylogenies using genome-wide properties that do not require the initial recognition, assignment or alignment of homologous characters. These alignment-free methods compute the distance between genomes based on such features as the frequencies of particular strings of nucleotides or amino acids but can also involve sequence motifs or protein folds and domains. Many of the genomic signatures applied in early studies, such as overall base composition, dinucleotide frequencies, and amino acid or codon usage patterns, contain only weak phylogenetic signals due to convergence and the lack of character complexity. However, there has been a substantial increase in the use and accuracy of such alignment-free methods because they are often computationally less intensive and offer a means to phylogenetically classify sequences, such as those generated in large-scale metagenomic surveys, in which homology assignment is impossible.

Other Applications of Phylogenetics

Functional Predictions

Phylogenetic analyses of all homologues within multiple completed genomes have the capacity to provide in-depth insight into the level of evolutionary and functional diversification within a particular gene family. This method relies on distinguishing sets of orthologous genes (inherited vertically through speciation) within a single phylogeny, with paralogous genes (acquired through gene duplication) representing new functional groups (Figure 2). By including functionally characterized reference proteins for each major monophyletic group, functional assignment of related orthologues can sometimes be inferred. It is notable that HGT can greatly complicate these types of analyses, as xenologous genes (genes acquired through horizontal transfer) may often be mistaken for orthologues or paralogues.

Figure 2 Phylogenetic inference of function involves generating a phylogeny of all homologues within single genomes (taxa A–F) and identifying orthologous groups (Group I, II, and III). Paralogues (A2 and A3 are paralogous to A1) may represent functionally distinct subgroups.

The use of such methods to understand protein evolution has increased substantially over the last several years, attributable to the dramatic increase in the availability of fully sequenced microbial genomes. For example, bacterial porins comprise a large family of proteins, which serve as channels through which solutes are exported out of the bacterial cell across the outer membrane. NmpC, OmpF, OmpC, and PhoE are well-characterized porin proteins that differ in solute specificity, but also exhibit sufficient evolutionary divergence and form clear monophyletic groups. A phylogenetic analysis of the porin family of proteins from the enteric bacteria, including both characterized and putative porins, resulted in the assignment of 30 putative porins to specific functional (solute-specific) groups. Two new porin groups also emerged – the OmpF2 and PhoE groups – suggesting additional diversification of specific orthologues, possibly through independent gene duplication events. Interestingly, the new PhoE group comprises proteins solely from species of *Yersinia*, and these may have evolved more recently via duplication due to porin antigenicity. Thus, the application of phylogenetic techniques has permitted a comprehensive analysis and characterization of the bacterial porins and the assignment of uncharacterized homologues to existing functional groups.

Phylogenetic approaches have also been used to identify evolutionarily and functionally relevant motifs within protein families, providing insight into both enzyme structure and biochemical mechanisms of action. La and colleagues, in 2005, conducted a sliding window analysis on a sequence alignment of the orthologues of the triosephosphate isomerase protein family to identify those residues that recover the overall family topology. Motifs that recover the complete sequence phylogeny are predicted to be functional sites and can subsequently be tested experimentally. In this study, predicted functional sites were tested by mapping them onto closely related protein structures, revealing that many corresponded to protein loops, active sites, and other structures, and illustrating the effectiveness of this phylogenetic approach in identifying residues responsible for protein structure and function.

Coevolution and HGT

Phylogenetic analyses have the potential to identify both uniformities in evolutionary patterns and deviations from expected patterns. For example, the comparison of evolutionary histories can identify cases of cospeciation, where long-term association is manifested in fully congruent phylogenies that denote organisms having very similar or identical evolutionary histories (Figure 3). Undoubtedly, one of the best studied cases of coevolution, identified using phylogenetic methods, is that of the aphid and its nutritional association with the bacterium *B. aphidicola*. *Buchnera* supplements the aphid diet of nutrient-deficient phloem sap with essential amino acids, including leucine and tryptophan, resulting in a long-standing, obligate association. Indeed, comparisons of the evolutionary history of *Buchnera*, as established by 16S rDNA phylogenies, with that of their aphid host species revealed phylogenetic congruence, illustrating the mutualistic association of *Buchnera* with the aphid prior to the divergence of extant aphid families. In an interesting twist, *B. aphidicola* 16S and *dnaN* gene genealogies were also congruent to those of the plasmid-encoded amino acid biosynthesis genes *trpEG* and *leuABC*, suggesting stable coexistence of plasmids with their *Buchnera* hosts. This sort of mutualistic association, involving a eukaryote, a bacterium, and its transmissible genetic elements is relatively unique, and serves to illustrate the power of phylogenetic analyses in establishing evolutionary mechanisms of coevolution.

Coevolutionary processes also appear to be maintaining the mutualistic relationships of bioluminescent *Vibrio fischeri* bacteria and squid. A comparison of molecular phylogenies of internal transcribed spacer and the cytochrome oxidase subunit I of the squid mitochondrial DNA to those obtained from the bacterial *gapA* gene revealed similar evolutionary histories, reinforcing maintenance of coevolutionary processes. Because the bacteria are environmentally acquired, this parallel evolution strongly implicates host-

Figure 3 (a) Phylogenetic inference of coevolution, as resolved by comparing tree topologies. Congruent phylogenies are indicative of similar evolutionary histories for a given set of taxa (A–G, 1–7), and thus, cospeciation. (b) Incongruent tree topologies may indicate horizontal gene transfer (HGT) among organisms.

specific associations between symbiont partners. These phylogenetic inferences were further validated through competitive colonization assays, which illustrated that specific *V. fischeri* strains preferentially colonize their evolutionary counterparts.

Phylogenetic approaches have also been used to solve longstanding questions pertaining to the origins of new genes in the evolution of microbes and eukaryotes. The role of HGT in the evolution of bacteria has been well documented; however, the occurrence of HGT among eukaryotes, and its influence on the diversification of this domain, has remained a controversial topic in eukaryotic evolutionary biology. One early study by Bork and colleagues, in 1992, focusing on the evolution of the fibronectin type III domain (Fn3), reported its possible transfer to the bacteria. Although phylogenetic analyses revealed that the bacterial Fn3 proteins were monophyletic, a transfer event was favored due to the fact that (1) the bacterial sequences were more closely related to the animal sequences than expected by sequence divergence, (2) the Fn3 domain was represented sporadically in bacteria, and (3) it was not identified in either plants or fungi. The Fn3 domain, however, was later identified in a plant protein, suggesting that sampling bias was likely responsible for the seemingly limited distribution of the Fn3 domain in the original study.

With the sequencing and analysis of the human genome in 2001 came the report of a purported 223 cases of HGT between bacteria and vertebrates. Criteria for identifying these HGT events included a top BLAST hit to a bacterial gene and absence from a nonvertebrate genome. Of the 223 potentially acquired genes, only 28 had been confirmed to be present within the genome subsequently and served as the focus of a systematic phylogenetic analysis to determine the likelihood of HGT between bacteria and vertebrates. Of these 28 genes, 23 clustered with a nonvertebrate eukaryote positioned at the base of the tree (and were therefore not likely cases of HGT), whereas the remaining five cases were deemed ambiguous cases of HGT. Thus, although the vast majority of HGT cases reported in the original study were due to the absence of appropriate phylogenetic analyses; however, HGT between bacteria and vertebrates could not be discounted entirely. There was also some suggestion of bacterial contamination as a plausible explanation for the observed transfer events, which was later confirmed to be a contributing factor to the HGT events reported in the original study.

Phylogenetic approaches have been central to our ability to identify cases of horizontal transfer, even between distantly related organisms such as bacteria and eukaryotes. An increasing number of studies are employing phylogenetic and other methods to understand HGT and its impact on eukaryote evolution, with many studies providing evidence for HGT between the three domains of life.

Glossary

Gut microbiome The complex community of many bacterial species in the human intestine.

Kinesin Motor proteins that use energy released by ATP hydrolysis to move toward the (+) end of a microtubule, transporting vesicles or particles in the process.

Metagenome Genome sequences from an entire community of microbes in a natural habitat such as an environmental aquatic or soil habitat or within or on a biological organism and its tissues.

Metagenomics The technique of direct genome sequencing of an entire community of microbes in a natural habitat, bypassing the need to isolate and culture individual bacterial community members. The major aim is often to determine the structure and diversity of the species present in the community, but it can also be applied to retrieval of particular functional gene classes *e.g.*, for use in biotechnology and ‘microbial prospecting’. In the community diversity version of such techniques, the sequences from a mixed metagenome have to be assembled and sorted (‘binned’) computationally for analysis of the structure of taxonomic phylum- or species-level diversity within the community.

Microtubules Cytoskeletal fibers typically found in cells of eukaryotes and in eukaryotes formed by polymerization of alpha- and beta- tubulin monomers which exhibit structural and functional polarity. In eukaryotes they are important components of cilia, flagella, the mitotic spindle, and other cellular structures. In eukaryotes they are 24 nm in diameter.

Mucin An important component of the mucus layer lining the human intestinal epithelium. Mucins are produced by goblet cells of the intestinal epithelium, and are highly glycosylated molecules also including serine, threonine and cysteine amino acids, and they form a transparent mucus layer on the intestinal tissue surface, containing in the colon a substantial bacterial community.

Prosthecae Rigid appendages of bacterial cells bounded by the cell wall, including stalk-like and hypha-like appendages of *Caulobacter*, *Asticacaulis* and *Hyphomicrobium* species in phylum *Proteobacteria*, projections of the cell surface in *Prosthecomicrobium* and *Ancalomicrobium* species in phylum *Proteobacteria*, and the stalk-like and wart-like projections of the cell surface in phylum *Verrucomicrobia* members *Prosthecobacter* species and *Verrucomicrobium spinosum*. They are projections of the cell cytoplasm and cell wall in such a way as to make the shape of the cell distinct from the classical rod or sphere shape of bacterial cells. Their contents are continuous with the cytoplasm of the rest of the cell.

PVC *Planctomycetes-Verrucomicrobia-Chlamydiae* superphylum grouping of phyla *Planctomycetes*, *Verrucomicrobia* and *Chlamydiae* but also members of phylum *Lentisphaerae*, phylum *Omnitrophica* and possibly phylum *Poribacteria*. The phylum as a whole is grouped in a larger PVC superphylum with members of the distinct phyla *Planctomycetes*, *Chlamydiae*, *Lentisphaerae* and *Omnitrophica* (formerly phylum OP3), and the phylum *Kiritimatiellaeota* originally a subdivision of the *Verrucomicrobia* phylum. The member phyla cluster together in phylogenetic trees based on gene sequences such as a 16S rRNA but some phyla also share at least one marker protein and some members of separate PVC phyla such as *Planctomycetes*, *Verrucomicrobia* and *Lentisphaerae* share cell structure features such as internal membrane development and probably membrane-bounded internal compartments.

Rhizosphere The interface between plant roots and soils, known to contain an enriched population of largely soil-derived microbial diversity, influenced by deposition of plant mucilage and root exudates.

Tubulin Globular cytoskeletal proteins that in eukaryotes have the ability to polymerize to form microtubules.

Verrucomicrobia A phylum-level group of the domain Bacteria named after one of the notable species described relatively early in the history of the discovery of the phylum, *Verrucomicrobium spinosum*. The phylum is a member of the PVC superphylum.

Introduction

The phylum *Verrucomicrobia* is an excellent example of the fascinating insights for microbiology to be gained from the study of diverse types of bacteria. The phylum was originally defined (Hedlund et al., 1997) on the basis of two genera, *Verrucomicrobium* and *Prosthecobacter*, and was only recognized by application of 16S rRNA gene sequencing (Albrecht et al., 1987; Hedlund et al., 1996) – *Prosthecobacter* had been originally suggested to be a close relative of *Caulobacter*, a member of phylum *Proteobacteria*, on the basis of morphological similarities (Staley et al., 1976). *Verrucomicrobium spinosum* was the first to be sequenced and a new bacterial division suggested as most suitable for its diverse phylogenetic position relative to other bacteria (Albrecht et al., 1987). At least 5 subdivisions of phylum *Verrucomicrobia*, comprising species forming closely related clusters within the 16S rRNA-based phylogenetic tree of the phylum, were initially recognized (mostly from analysis of uncultured sequences); one of these, subdivision 5, is distant and distinct enough to have been later proposed as a separate new bacterial phylum *Kiritimatiellaeota* (Spring et al., 2016),

and *Victivallis vadensis*, originally viewed as a member of a subdivision 7, is now known to be a member of separate phylum *Lentisphaerae* (Cho et al., 2004). The acidophilic methylotrophic verrucomicrobia (see below) have been referred to as members of a subdivision 6, and certainly form a distinct cluster within *Verrucomicrobia*. Verrucomicrobia have since their initial recognition contributed substantially to our knowledge of the range of diversity of bacterial cell biology, potential origin of proteins characteristic of eukaryotes, the significant role of these previously undetected bacteria in soil ecology, and the key roles such diverse bacteria may play in the human gut microbiome. The phylum *Verrucomicrobia* derives its name from the first cultured species isolated, *Verrucomicrobium spinosum* (Schlesner, 1987), so-called because of the resemblance of projections of the cell surface to human skin warts (*Verrucomicrobium* is derived from the Latin word *verruca* meaning a wart). These surface projections are now known to be true 'prosthecae' or projections of the cell wall including some cytoplasm (rather than external appendages).

The phylum *Verrucomicrobia* is now known to be related to several other phyla of the bacteria forming a cluster called a superphylum, including the phyla *Planctomycetes* and *Chlamydiae* as well as phylum *Lentisphaerae* and the 'Candidate phylum' *Omnitrophica* (Rinke et al., 2013), and possibly including other phyla of uncultured bacteria. The superphylum is known as the PVC superphylum (*Planctomycetes-Verrucomicrobia-Chlamydiae*) (Wagner and Horn, 2006; Fuerst, 2013). Phylogenetic and indel analysis supports the relationship of *Verrucomicrobia* and *Chlamydiae*, and at least one shared superphylum-specific signature protein is consistent with the grouping of phyla *Planctomycetes*, *Verrucomicrobia*, *Chlamydiae*, *Lentisphaerae* and *Omnitrophica* (Gupta et al., 2012; Lagkouvardos et al., 2014). The relationship of *Planctomycetes* and *Chlamydiae* was first recognized via shared features of 16S rRNA seen via oligonucleotide analysis (Weisburg et al., 1986). Consistent with the evolutionary relationship indicated by phylogenetic analysis, the group may also share some features of cell structure and biology which will be discussed below in more detail.

Our knowledge of the diversity of phylum *Verrucomicrobia* has been from very early in its history the result of a combination of study of cultured isolates and direct metagenomics studies of natural mixed microbial communities such as those in soil, resulting in clusters in phylogenetic analyses of rRNA sequences recognized as distinct subdivisions (Hugenholtz et al., 1998). After the initial discovery of verrucomicrobia members and the establishment of *Verrucomicrobia* as a bacterial division (Hedlund et al., 1997) which later became a phylum of the Bacteria (Hedlund, 2011b), five subdivisions were delineated (Hugenholtz et al., 1998) via 16S rRNA phylogenetics, comprising both cultured named species and many uncultivated sequences. Later, formal Class-, Order- and Family-level taxonomic categories (Hedlund, 2011b) were established for some Divisions such as subdivision 1 proposed as equivalent to the class *Verrucomicrobiae*, subdivision 2 (class *Spartobacteria*) (Sangwan et al., 2004) and subdivision 4 (class *Opitutae*) (Choo et al., 2007). Class *Verrucomicrobiae* now contains families *Rubritalaceae* and *Akkermansiaceae* as well as the original family *Verrucomicrobiaceae*, and interestingly these families seem to correspond to habitats – marine habitats for *Rubritalaceae*, animal intestines for *Akkermansiaceae* and freshwater for *Verrucomicrobiaceae* (Hedlund, 2011a). The subdivision system (sometimes 'subphylum' is used)- is also still widely referred to, since it can be used for clusters of sequences from culture-independent studies. However, members of subdivision 5 have recently been proposed as members of a new separate phylum, *Kiritimatiellaeota* (Spring et al., 2016). Some other verrucomicrobia members such as the methane-oxidizing acidophilic and thermophilic *Methyloacidiphilum* do not fit into the original subdivisions, and have been proposed as members of the new family *Methyloacidiphilaceae*, (Op den Camp et al., 2009) but have also been referred to as subphylum 6 in the formal classification authority Bergey's Manual (Hedlund, 2011b).

Why are They Important?

The verrucomicrobia are an especially important group of bacteria from many perspectives. They have evolutionary and cell biology significance regarding their relationship to other bacterial phyla such as *Chlamydiae* and *Planctomycetes* with complex cell structure or biology, and the intriguing presence of close homologs to eukaryotic proteins such as tubulins. Some species display unusual projections of cell cytoplasm and wall called prosthecae, and may also contain membrane-bounded cell compartments unusual in Bacteria but present in the related phylum *Planctomycetes*. They are of immense significance to understanding of ecology, especially of the ecology of soil microbial communities and their function, since they appear to be a widespread and quantitatively significant component of soils throughout the planet. They may also play important roles in other natural ecosystems such as marine and fresh waters. Finally, certain species such as *Akkermansia muciniphila*, may play key roles in the microbial communities of animal guts, including humans, where understanding of such verrucomicrobia may prove of central importance to understanding diseases associated with the human intestine and the widespread and increasing modern problems of human obesity and diabetes. Initially thought to be mainly aerobic heterotrophs, the diversity of verrucomicrobia has yielded surprising new forms of physiology, such as the acidophilic and thermophilic methanotrophy of verrucomicrobia such as *Methyloacidiphilum* species, of significance in understanding bacterial methane oxidation and the full range of bacteria involved in global cycling of methane, an important greenhouse gas. Each of these aspects of the verrucomicrobia are dealt with in detail below.

Isolation, Culture and Physiology

The first representatives of the phylum *Verrucomicrobia* such as *Verrucomicrobium spinosum* and *Prostheco bacter* species such as *P. dejongeii* were isolated as aerobic chemoorganotrophs from aquatic habitats (Schlesner, 1987; Staley et al., 1976). Later studies systematically exploring soil bacteria expanded the named genera and species of cultured heterotrophic strains by use of very low

nutrient media and the replacement of potentially inhibitory agar as a gelling agent in solid media by polymers such as gellan (Janssen et al., 2002), and this approach was expanded to the use of polymeric carbon and energy sources such as xylan known to occur on soil and the use of both extended incubation times (e.g., 1 month) and concentrated inocula (Sangwan et al., 2005). Interestingly, some verrucomicrobia such as *Brevifollis gellanilyticus* and *Luteolibacter gellanilyticus* actually appear capable of degrading the gellan polymer recommended for soil verrucomicrobia isolation (Otsuka et al., 2013; Pascual et al., 2017). Heterotrophic Verrucomicrobia have affinity for carbohydrate carbon and energy substrates, and sometimes a mixture of sugars (at concentration of 1 mM each) have also been used as substrates in isolation media (Janssen et al., 1997). Members of the family *Opitutaceae* in subdivision 4 such as *Opitutus terrae* from rice paddy soil were originally reported to be obligate anaerobes (Chin et al., 2001) but more detailed investigations indicate that *O. terrae* for example is facultatively anaerobic and can tolerate at least some oxygen (Tegtmeier et al., 2018). Both cultural and genome evidence indicate that a verrucomicrobia species within *Opitutaceae* (initially named *Diplosphaera colitermitum* but later revised to *Geminisphaera colitermitum*) is microaerophilic, growing optimally between 2 and 8% oxygen, and is also able to fix nitrogen (Wertz et al., 2012). Anaerobic Isolates from rice paddy soil that later were shown to be related to the verrucomicrobia genus *Opitutus* were reported to possess ‘ultramicrobacteria’ cell sizes, with average cell volumes of only 0.03–0.04 μm^3 (cells are 0.35 μm wide compared to *V. spinosum* at 0.8–1.0 μm wide) (Janssen et al., 1997); the small cell size was not a feature due to starvation but was independent of substrate concentration used for culture. Such isolates seem to be in substantial numbers in their habitat (e.g., $1.2\text{--}7.3 \times 10^5$ cells per g of dry soil), since a liquid dilution series followed by anaerobic agar tube dilution series was used for their isolation. It is of interest that at least one widely distributed uncultured soil verrucomicrobial bacterium, ‘*Candidatus Udaeobacter copiosus*’ has a genome of only 2.8 Mbp, suggesting genome reduction associated with large population size combined with selection against metabolic versatility (Brewer et al., 2016). A number of members of distinct verrucomicrobial genera have been isolated from marine habitats (Choo et al., 2007) and may have some unusual cell wall features (see below) e.g., a species such as *Coralimargarita akajimensis* a member of subdivision 4 (Yoon et al., 2007c), and *Cerasicoccus arenae* from marine sand, proposed as representative of a family *Pumiceicoccaceae* of marine species in the subdivision 4 Class *Opituta* (Yoon et al., 2007a). Simple media widely used in marine microbiology such as a diluted seawater version of marine agar 2216 were used for isolation of the marine verrucomicrobia (see for example for *Coralimargarita akajimensis* (Yoon et al., 2007c)).

The important human and animal gut microbial community species *Akkermansia muciniphila* was isolated as an anaerobic mucin-degrader via dilution of faeces in anaerobic medium with gastric mucin as sole carbon source combined with purification via anaerobic soft agar subculture (Derrien et al., 2004).

Aerobic methane-oxidizing verrucomicrobial acidophilic thermophiles such as *Methylocaldophilum infernorum* and *Methylocaldophilum fumariolicum* were isolated from geothermal habitats such as methane-rich geothermally heated soil or mudpots near volcanic fumaroles (Dunfield et al., 2007; Pol et al., 2007), and these species grow optimally at pH 2.0–2.5 and 60°C and at a pH 0.8 and a temperature of 50°C respectively. Mesophiles have also been isolated from volcanic soil, such as *Methylocaldimicrobium* spp., even more acid-tolerant than their thermophilic relatives; one species, *M. tartarophylax*, can grow even at pH 0.5 (van Teeseling et al., 2014). Interestingly, such isolates may have a streamlined genome (e.g., 2.3 MBp in *M. infernorum* – (Hou et al., 2008)) with limited potential for gene expression regulation. The genuine autotrophic dependence of these methane oxidizers on CO_2 as sole carbon source is indicated by genomic and transcriptomic data; in *Methylocaldophilum fumariolicum* all genes required for a functional Calvin-Benson-Bassham (CBB) cycle are transcribed (Khadem et al., 2011). Methane is apparently used mainly as an energy source via its oxidation rather than as a carbon source (so activity of methanotrophs would be missed by methods depending on isotopically labeled methane). This organism also has a unique type of RuBisCo CO_2 fixation enzyme. The species is also capable of nitrogen fixation and possesses an extremely oxygen-sensitive nitrogenase (Khadem et al., 2010). *M. fumariolicum* can also oxidize hydrogen using carbon dioxide as a sole carbon source, so can be independent of methane as an energy source under some conditions, at least in oxygen concentrations less than 1.5% (Mohammadi et al., 2017). From direct studies of verrucomicrobia-dominated soil communities from an acidic geothermal field and data from a *Methylocaldophilum* isolate from those soils it appears that verrucomicrobial methanotrophs can use a strategy of mixotrophy to grow optimally in their natural geothermal methane- and hydrogen-rich habitats, by combining both methane- and hydrogen-oxidizing abilities, allowing expansion into wider niches than methane oxidation alone would allow (Carere et al., 2017).

Remarkably, growth of the volcanic mudpot verrucomicrobium *Methylocaldophilum fumariolicum* SolV is strictly dependent on the lanthanides, rare earth elements such as lanthanum, cerium, praseodymium and neodymium, which act as cofactors for methanol dehydrogenase, a key enzyme for methane oxidation (Pol et al., 2014).

Since methane is a potent greenhouse gas, and methanotrophic verrucomicrobia occupy unique and methane-rich habitats, it has been suggested that they could be an important contributor to reducing greenhouse gases contributing to global warming, since they can limit the amount of biologically or geochemically produced methane escaping into the atmosphere (Mohammadi et al., 2017) – this would imply that verrucomicrobial methanotroph ecology could be important to understand for global greenhouse gas modeling.

Genomes of verrucomicrobia have revealed potential for microbial sulfite/sulfate reduction ability, indicated by genes for dissimilatory sulfite reductases (DsrAB) which may include some of the earliest evolved such genes (Anantharaman et al., 2018).

Genomic data of verrucomicrobia and other members of the PVC superphylum is now extensive, and new databases available should ameliorate exploration of their genomes and proteomes for comparative studies and make understanding of their metabolome and cell biology-relevant genes more feasible (Bordin et al., 2018). The PVCBase database is a simple portal for published genomes of cultured verrucomicrobia (See Relevant Websites Section). Many more unpublished verrucomicrobia genomes are available in such genome databases as NCBI Genome (See Relevant Websites Section) or IMG – JGI’s Integrated Microbial Genome and Microbiomes

(See Relevant Websites Section). At least draft genomes exist for named species *Verrucomicrobium spinosum* in class *Verrucomicrobiae* (see “Relevant Websites section”), *Akkermansia muciniphila* of class *Verrucomicrobiae* both as a cultured isolate (van Passel et al., 2011b) and from a whole genome assembly from uncultured cells from human faecal material (Caputo et al., 2015), *Terrimicrobium saccharophilum* (Qiu et al., 2017) and the uncultured ‘*Candidatus* Udaeobacter copiosus’ and *Chthoniobacter flavus* (Sangwan et al., 2004), all in Class *Spartobacteria* (Brewer et al., 2016), *Opitutae terrae* in Class *Opitutae* (van Passel et al., 2011a), *Pedospaera parvula* of subdivision 3 (Kant et al., 2011), and *Methyloacidiphilum infernorum* representative of the acidophilic methanotroph ‘subdivision 6’ (Hou et al., 2008). Cultured named species vary from the ‘streamlined’ 2.3 Mbp and 2.66 MBp genomes of *Akkermansia muciniphila* and *Methyloacidiphilum infernorum* to the substantial 7.8 Mbp genome of *Chthoniobacter flavus*.

Culture-independent sequencing studies of metagenomes from natural microbial communities indicate that only a limited number of species existing in nature have been isolated in each subdivision or Class of *Verrucomicrobia*, e.g., in soil, verrucomicrobia of class *Spartobacteria* appear especially significant but isolates do not represent the known phylogenetic breadth from culture-independent studies (Janssen, 2006), so there seems to be a vast wealth of verrucomicrobial species remaining to be cultured and described.

Distribution and Ecology Including Importance in the Soil Ecosystem

Verrucomicrobia are mostly free-living bacteria and can be found in freshwater, marine, soil and animal gut habitats. They appear to be globally distributed in both freshwater (Zwart et al., 1998) and seawater (Freitas et al., 2012). They are prevalent in temperate freshwater lakes in northern USA, for example, comprising the 4th most abundant phylum of the bacterial community; verrucomicrobia were relatively particle-associated, and lake habitats vary in the particular Class or subdivision of verrucomicrobia dominating (Chiang et al., 2018). In a study of two contrasting freshwater habitats, a eutrophic lake and a humic bog, analysis of verrucomicrobia via metagenomics suggested their potential role as polysaccharide degraders in freshwater, and also revealed possible biochemical distinctions between strains inhabiting the two habitats and different layers within a habitat (He et al., 2017). Eutrophic lake verrucomicrobia are rich in glycoside hydrolases while verrucomicrobia in the upper lake layers possess an unusual class of genes for synthesis of cytochrome c usually considered specific for phylum *Planctomycetes*, an observation of great interest in light of the evolutionary relations of verrucomicrobia within the PVC superphylum. Bog verrucomicrobia possessed genes for unusual porin-multiheme cytochrome c complexes with a potential extracellular electron transfer function. In the Arctic marine water column, verrucomicrobia comprise one of the most frequently detected bacterial community members based on culture-independent 16S rRNA gene clone libraries, and may be associated with genes for hydrolyzing polysaccharides such as laminarin, chondroitin sulfate and xylan (Cardman et al., 2014).

The wide distribution in soils has been extensively documented - they appear to be dominant in many soil bacterial communities across the globe, and a molecular ecology study of 16S rRNA sequences using many different soils from biomes in Antarctica, Europe, and the Americas, as well as soils collected from a montane coniferous forest using data collected from surface horizons indicate that verrucomicrobia average 23% of all bacterial sequences present in the microbial communities (Bergmann et al., 2011). Appreciating such quantitative significance depended on designing and applying PCR primers which are not biased against this phylum when soil microbial DNA is used as substrate (Bergmann et al., 2011). The class *Spartobacteria* (subdivision 2) verrucomicrobia appear especially important in soils, with some evidence also for significance in some soils of subdivision 1 (Kielak et al., 2010), and “*Pedospaera parvula*” Ellin514 isolated from pasture soil (Sangwan et al., 2005) is one of the few cultured representatives of subdivision 3 of the phylum *Verrucomicrobia*. Complete genome sequences are available for two soil verrucomicrobial species, *Chthoniobacter flavus* from *Spartobacteria* subdivision 2 (Sangwan et al., 2004) and *Pedospadra parvula* from subdivision 3 (Kant et al., 2011). Verrucomicrobia are particularly significant numerically in grassland and prairie soils, perhaps as one suggestion has it due to relationships of some spartobacteria with soil nematodes since “*Xiphinematobacter*” a member of the Class *Spartobacteria* is nematode-associated (Bergmann et al., 2011), but this hypothesis remains to be investigated in detail. 16S rRNA from and qPCR performed on microbial communities indicate that Verrucomicrobia can be significant members of plant root - associated rhizosphere microbial communities (Kielak et al., 2008). Some studies suggest differences in rhizosphere association can occur between different strains of subdivision 1 verrucomicrobia (da Rocha et al., 2011). Verrucomicrobia occur as apparent symbionts with animals such as nematodes (Vandekerckhove et al., 2002), within the nuclei of protists in termite guts (Sato et al., 2014) and within marine tunicates (Lopera et al., 2017). Symbionts belong to at least two different subdivisions, the Classes, *Spartobacteria* and the *Opitutae*.

Verrucomicrobia do not appear to be pathogenic, but there is one report that *Verrucomicrobium spinosum* at least increases mortality rates in invertebrate model organisms *Drosophila melanogaster* and *Caenorhabditis elegans* (Sait et al., 2011), perhaps associated with the presence of a bacterial virulence factor Type III Secretion System (T3SS). The activity of *Akkermansia* is of relevance to susceptibility to effects of bacterial pathogens in the gut (at least in a germ-free mouse model) (Ganesh et al., 2013) as well as possible effects on protection against various intestinal and metabolic diseases described below.

Importance of Verrucomicrobial Genus *Akkermansia* for the Human Gut Microbiome and Related Disease

One species of the Verrucomicrobia, *Akkermansia muciniphila*, has been of very special interest and significance for understanding the microbial community of the human intestine, the gut microbiome. *Akkermansia* species occur in many different

animal species from pythons to horses as well as humans and model laboratory rodents (Derrien et al., 2017). As the species name *muciniphila* implies, this verrucomicrobial bacterium degrades mucin, an important component of the mucus layer lining the intestinal epithelium. Mucins are produced by goblet cells of the intestinal epithelium, and are highly glycosylated molecules also including serine, threonine and cysteine amino acids, and they form a transparent mucus layer on the intestinal tissue surface, containing in the colon a substantial bacterial community (Johansson et al., 2013). *Akkermansia muciniphila* is highly adapted to living from mucin degradation – for example it absolutely requires threonine for growth and has a variety of enzymes adapted for utilizing specialized sugars in mucin oligosaccharides such as sialidases and fucosidases and even sulfatases (Ottman et al., 2017a); it is also adapted to the low but definite oxygen concentration present in the mucus layer. Such adaptation suggests an advanced stage of coevolution between host animal and *Akkermansia* strains, and implies a potential functional significance of these verrucomicrobia for the host. This species may also be significant as a keystone species within the gut microbial community due to its supply of products of mucin degradation to other bacterial species (Chia et al., 2018). In mice, such a significance is suggested by correlations between increased abundance of *Akkermansia* in faeces of lean animals compared to the abundance in obese mice, and the observation that daily feeding of *Akkermansia* over a period of several weeks to mice with obesity induced by a high fat diet apparently reverses this induced obesity as well as improving epithelial integrity and related effects (Everard et al., 2013). The administration of *Akkermansia* to obese mice also results in an observed reduction in ‘metabolic endotoxemia’ via reduction of inflammatory lipopolysaccharides in the circulation, and in alleviation of insulin resistance (Everard et al., 2013; Shin et al., 2014) as well as cardiometabolic complications of obesity in mice such as arteriosclerosis (Li et al., 2016). At least conclusions from mice models regarding *Akkermansia* effects appear to be supported by replication from many different studies (Derrien et al., 2017).

There is also some data indicating that *Akkermansia* administration may form the basis for a protocol for obesity amelioration in human subjects (Sheng et al., 2018). Some data indicates the need for live *Akkermansia* cells to generate such effects in mice (Everard et al., 2013), but such protocols might eventually involve killed (pasteurized) cells or even purified *Akkermansia* proteins. Heat-killed cells of *Akkermansia* appear to have the same or even enhanced beneficial effects on high-fat-diet obese mice compared to effects of treatment with live cells (Plovier et al., 2017), and this is consistent with evidence that a protein associated with Type IV pili appendages in outer membranes of the cell wall may be the active component of *Akkermansia* cell effects in the mucin layer of the intestine. Outer membrane protein composition and especially the highly abundant pili-like protein Amuc_1100 of *A. muciniphila* assist host immunological homeostasis at the gut mucosa and improvement of the function of the gut barrier (Ottman et al., 2017b).

In summary, just one species of verrucomicrobia, *A. muciniphila*, may prove to be of dramatic significance to understanding human disease states of major importance to medicine.

Biotechnology

Verrucomicrobium spinosum possesses a tyrosinase with interesting properties of potential application in biotechnology (Fairhead and Thony-Meyer, 2010). There is also an interesting connection of the applied features of this tyrosinase with the concept that verrucomicrobia may retain some eukaryote-like characteristics – the tyrosinase of *V. spinosum* shares a feature of eukaryotic tyrosinases in that a C-terminal extension is present, one absent from tyrosinase of bacteria such as *Streptomyces*. Recombinant tyrosinase derived from *V. spinosum* can be used for protein cross-linking and immobilization, and has potential uses in preparing protein aggregates useful for industrial biocatalysis. Tyrosinases catalyze oxidation of phenols and possible applications include removal of phenols, biosensor fabrication, and for a production of biocompatible adhesives with medical applications (Axambayeva et al., 2018). Recombinant *V. spinosum* tyrosinase has been used to modify tyrosine residues in proteins to produce strong molecular adhesives with DOPA (3,4-dioxyphenylalanine) residues in place of tyrosines (Axambayeva et al., 2018). Other enzymes of biotechnological potential from *V. spinosum* and other verrucomicrobial species may be also worth exploring. For example, a novel approach has been used to recover genomes of active polysaccharide degraders from natural, complex microbial assemblages, employing fluorescently labeled substrates with fluorescence-activated cell sorting and single cell genomics to analyze freshwater and coastal bacterioplankton for degraders of laminarin and xylan (Martinez-Garcia et al., 2012). Genomic sequencing of just five cells, representing the most predominant polysaccharide-active *Verrucomicrobia* phylotype found, revealed significant enrichment in genes encoding a wide spectrum of glycoside hydrolases, sulfatases, peptidases, carbohydrate lyases and esterases. The potential thus exists for exploitation of such enzymes via genome mining even from uncultured verrucomicrobia.

Another potential product of verrucomicrobia is biopharmaceuticals. Cytotoxic compounds of the mandelalide class have been found in the marine tunicate *Lissoclinum* sp., and there is evidence from metagenomics that the compounds can be produced by the verrucomicrobial symbionts in the tunicate (Weyna et al., 2015). The symbiont, designated “*Candidatus Didemnitutus mandela*,” in a clade within the family *Opitutaceae*, possesses genes for synthesis of a type of trans-AT polyketides consistent with the mandelalide class (Lopera et al., 2017). The pathway appears functionally significant since the seven copies of the genes for mandelalide synthesis accounts for 19% of the symbiont’s genome by length, suggesting functional importance for chemical defense of the host tunicate animal. A metagenomics study of a marine kelp forest microbial community also suggests that verrucomicrobia may be a rich source of potential natural products in the polyketide compound class (Vollmers et al., 2017).

Cell Biology and Significance for Evolution

The verrucomicrobia possess some very interesting features relevant to bacterial cell biology and potential evolutionary interconnections between some features of cell biology characteristic of eukaryotes and those characteristic of bacteria. Their close relationship to *Planctomycetes* as PVC superphylum members suggests that some features of the planctomycete cell plan involving internal membranes and potential membrane-bounded compartments within cells might also occur in verrucomicrobia.

Cell Structure

The first described verrucomicrobia, *Verrucomicrobium spinosum* and *Prosthecobacter* species, displayed prosthecae, projections of the cell cytoplasm and wall which had first been described in members of phylum *Proteobacteria* such as *Ancalomicrobium* and *Prosthecomicrobium*. In *V. spinosum* (Fig. 1(A) and (B)) these are randomly distributed finger-like extensions from which fimbriae appendages project (Schlesner, 1987), while in *Prosthecobacter* (Fig. 2(A) and (B)) the prostheca takes the form of a single stalk-like structure (Staley et al., 1976). Only some genera of verrucomicrobia display prosthecae – so far only *Verrucomicrobium* and *Prosthecobacter* among the approximately 30 cultured genera have been described as prosthecate. Presence of prosthecae detectable by phase contrast microscopy has been used in isolation of prosthecate verrucomicrobia via colony screening (Hedlund, 2011a).

Features of cell ultrastructure consistent with the simplest forms of cell compartment bounded by a major intracellular membrane are displayed via transmission electron microscopy of cells of several species representing three verrucomicrobial subdivisions, *Verrucomicrobium spinosum* (see Fig. 1(B)), *Prosthecobacter dejongei* (see Fig. 2(B)) (both subdivision 1, *Verrucomicrobiae*), *Chthoniobacter flavus* (subdivision 2, *Spartobacteria*), and strain Ellin514 (now classed "*Pedosphaera parvula*" in subdivision 3) (Lee et al., 2009). The form of compartmentation is similar to the simplest form of cell compartment found in some of the species of phylum *Planctomycetes* such as *Pirellula staleyi* and in a member of the phylum *Lentisphaera*. A similar form of compartmentation has been found in subdivision 3 member *Limisphaera ngatamarikiensis* (Anders et al., 2015), and is claimed for a marine member of subdivision 4, *Coralimargarita akajimensis* (Pinos et al., 2016). Cells with this form of compartmentation have been proposed to

Fig. 1 (A) Transmission electron micrograph of negatively-stained cell of *Verrucomicrobium spinosum* showing many tube-like prosthecae projections on all regions of the cell surface. Bar marker 1 μm . Micrograph from Jeffrey Lee of the author's laboratory. (B) Transmission electron micrograph *Verrucomicrobium spinosum* sectioned cell (cryofixed via freeze-substitution method), showing major ribosome-containing cell compartments bounded by internal membrane, other ribosome-free regions, and the cytoplasmic and cell wall-bound nature of the prosthecae projections of the cell. Bar marker 1 μm . Micrograph from Jeffrey Lee of the author's laboratory.

Fig. 2 (A) Transmission electron micrograph of negatively-stained cell of *Prosthecobacter dejongeei* showing single stalk-like prostheca projection on one pole of the cell only. Bar marker 1 μm . Micrograph from Jeffrey Lee of the author's laboratory. (B) Transmission electron micrograph *Prosthecobacter dejongeei* sectioned cell (cryofixed via freeze-substitution method) showing cytoplasmic nature of interior of the single stalk-like prostheca projection and cell compartmentation into major regions containing ribosomes and a less extensive ribosome-free region. Bar marker 0.5 μm . Micrograph from Jeffrey Lee of the author's laboratory.

possess a major membrane-bounded 'pirellosome' compartment containing the nucleoid DNA and ribosomes, and an outer ribosome-free 'paryphoplasm', analogous to the cell regions in the planctomycete cell plan (Fuerst and Sagulenko, 2011, 2013). The closed nature of such compartments needs confirmation by cryoelectron tomography, but it is clear that there is a major internal membrane development in cells of some representative cultured verrucomicrobia.

Via electron cryotomography, remarkable external appendages have been observed on cells of *Prosthecobacter debontii*, ca. 20×50 nm in dimensions and having a complex disc- and multiple 'leg' structure, not observed previously in bacteria and of unknown function (Dobro et al., 2017).

Verrucomicrobia stain Gram-negative, and would be expected to possess cell wall characteristics of other Gram-negative bacteria including an outer membrane with lipopolysaccharide (for which genomic evidence exists – (Speth et al., 2012)), and the classical and almost universal bacterial cell wall polymer peptidoglycan (PG), with diaminopimelic acid common in Gram-negative peptidoglycan as well as muramic acid. Verrucomicrobia originally discovered such as *Verrucomicrobium spinosum* were found to indeed possess peptidoglycan. However, there are some reports in newly described marine species in family *Puniceococcaceae* within class *Opitutae* of the absence of peptidoglycan evidenced by the absence of muramic acid and diaminopimelic acid in wall analyses e.g., *Pelagiococcus* species (Yoon et al., 2007b,d), *Cerasiococcus* spp. (Yoon et al., 2007a, 2010), and *Coralimargarita akajimensis* (Yoon et al., 2007c). It has been noted however that at least *Coralimargarita akajimensis* possesses genes consistent with peptidoglycan synthesis ability, and PG analysis of some other subdivision 4 *Opitutae* strains indicates that thin-layer chromatography is not suitable as an analysis method for detecting the low amounts of peptidoglycan in cells of some subdivision 4 strains (Rast et al., 2017); walls of marine *Puniceococcaceae* had however been investigated with HPLC amino acid analysis as well as thin-layer chromatography (Yoon et al., 2007a). One reason for difficulty in detecting peptidoglycan in some species may be low proportional

amounts of peptidoglycan relative to cell mass, as indicated by the data on *Limisphaera ngatamarikiensis* where only trace amounts of peptidoglycan-specific meso-diaminopimelic acid were detected (Anders et al., 2015). Lipopolysaccharide and outer membrane proteins characteristic for Gram-negative bacterial walls have been found in the significant gut verrucomicrobium *Akkermansia muciniphila* (Ottman et al., 2016).

Symbiotic verrucomicrobia called epixenosomes found associated closely with the surfaces of the marine ciliate protozoan *Euplotidium* have a complex compartmented internal structure including an 'extrusive apparatus' which may be ejected under certain stimuli and which have been proposed to have a defensive function for the host protozoan against another predator ciliate (Petroni et al., 2000), and cytoskeletal features of evolutionary interest (see below).

Tubulins and Other Cytoskeletal Proteins

Via genome sequencing, two genes *btuba* and *btubb* with close similarity to eukaryotic tubulins were discovered in verrucomicrobia member *Prostheco bacter de j ong e i i*, and homologs confirmed in three other species of this genus, *P. debontii*, *P. fusiformis* and *P. vanneervanii* (Jenkins et al., 2002). The corresponding deduced tubulin proteins BtubA and BtubB had properties consistent with their homology to tubulins rather than to the common bacterial tubulin family FtsZ cell division protein. This is evolutionarily significant since tubulins are essential for formation in eukaryote cells of microtubules, cytoskeletal assemblies functioning in several important ways in providing motors for organelle transport within the cell and for movement of materials in mitotic segregation during cell division. BtubA and BtubB were shown to share 31%–35% and 34%–37% sequence identity with eukaryote α and β tubulins; BtubA and BtubB were shown to contain each of the nine motifs specific to eukaryotic tubulin but only two to three of the six signatures for bacterial FtsZ, indicating a closer relationship to tubulins than FtsZs. *Btuba* and *btubb* were adjacent to each other on the genome. Phylogenetic analysis in that study indicated that neither BtubA or BtubB clustered with tubulins of any specific extant eukaryotic clade, and that the bacterial tubulin sequences were always seen to branch more deeply than eukaryotic tubulins; so there was no indication from that analysis of likely horizontal gene transfer as an explanation for the eukaryotic-like tubulin occurrence in a bacterial species, and the alternative of close relationship with a shared tubulin-like ancestral protein was also considered in this initial study. Another species of *Prostheco bacter*, *P. fluvialis*, does not (based only on attempted PCR amplification but using tubulin +ve *P. vanneervanii* as a positive control) appear to possess tubulins (Takeda et al., 2008), but does apparently possess a prosthecae stalk, which has been used to argue that the tubulin function in other *Prostheco bacter* spp. cannot be concerned with formation of prosthecae.

However, EM examination of cryo-fixed sectioned cells of the three other named *Prostheco bacter* species, *P. de j ong e i i*, *P. vanneervanii*, and *P. debontii*, in comparison with a mutant strain lacking *btubAB* genes, demonstrated tube-like structures in wild-type strains of *btubAB* positive species, localized to the prosthecae stalk or in the transition zone between stalk and cell body (Pilhofer et al., 2011). Cryo-fixation (as used for the EM preparation technique of freeze-substitution) is necessary to preserve such structures.

The more typical member of the tubulin family in Bacteria, *ftsZ*, has been found to co-occur with tubulins in *Prostheco bacter* species (Pilhofer et al., 2007b), and FtsZ alone has been found to occur in *Verrucomicrobium spinosum* (Yee et al., 2007). FtsZ was found in all three *Prostheco bacter* species where tubulins are found - *P. de j ong e i i*, *P. debontii* and *P. vanneervanii*. The co-occurrence of FtsZ was interpreted as support for horizontal gene transfer as the origin of tubulins (Pilhofer et al., 2007b), but phylogenetic analysis of FtsZ of *V. spinosum* suggested a deep branching position and ancient origin for that protein (Yee et al., 2007). Later more detailed studies of *Prostheco bacter* tubulin structure suggest that if HGT did occur from eukaryotes, it must have been a very ancient transfer, since the tubulin structure is compatible with an ancient form of the structure (Martin-Galiano et al., 2011). From considerations such as primitive assembly properties, it has been proposed that BtubA/B were acquired by *Prostheco bacter* in evolutionary time not long after an alpha- and beta-tubulin ancestor protein's duplication, possibly from a primitive eukaryotic cell via horizontal gene transfer (Martin-Galiano et al., 2011). Considerations of gene order surrounding the FtsZ gene and genes classically associated with FtsZ in other bacteria suggested that in verrucomicrobia a typical bacterial FtsZ-based cell division operates rather than one based on tubulin as in eukaryotic mitosis (Pilhofer et al., 2007b).

The BtubA/BtubB system has been subjected to considerable study regarding polymerization and other properties relevant to any comparison with eukaryotic tubulins and microtubule polymerization. It was first found that mixtures of BtubB and BtubA (purified from proteins cloned in *E. coli*) were capable of forming long protofilament bundles, 4–7 protofilaments wide (20–30 protofilaments in the three-dimensional bundle) (Sontag et al., 2005), and that BtubB possessed GTPase activity. Protofilament composition suggested that BtubA and BtubB alternate along the protofilament, and a cooperative assembly mechanism was suggested. Protofilaments formation BtubA/B does not need folding-assisting chaperonin proteins, unlike eukaryote tubulins (Schlieper et al., 2005). Crystallography studies of BtubA purified after cloning and expression in *E. coli* and of polymerized BtubA/B heterodimer demonstrated that the structure of BtubA/B is much closer to eukaryotic tubulins than to bacterial FtsZ and includes surface loops unique to tubulin, and also a C-terminal domain used in eukaryote tubulins for interactions with microtubule-associated proteins (Schlieper et al., 2005). Such eukaryote-adapted features, together with the largely bacterial nature of the *Prostheco bacter* genome, have been used to argue for an origin of verrucomicrobial tubulins via horizontal gene transfer from eukaryotes (Schlieper et al., 2005).

BtubA and BtubB do not seem to correspond exactly to the alpha and beta classes of eukaryote tubulin, rather they have mixed features of both classes in each, forming a mosaic of residues intermingling features of alpha and beta tubulins (Martin-Galiano et al., 2011). These features combined with the biochemical simplicity of the system have been used to support a scenario in which

bacterial tubulins originated from simple forms of tubulin genes that were transferred from a primitive eukaryotic cell rather than any modern lineage of eukaryotes, consistent with why the Btub sequences are mosaics of alpha and beta tubulins and why no existing eukaryotic donor is identifiable *e.g.*, BtubA and BtubB are divergent from any modern eukaryote lineage in phylogenetic trees of tubulins (Martin-Galiano *et al.*, 2011). A phylogenetic analysis of *V. spinosum* FtsZ indicating deep-branching position is consistent with a deep-branching tubulin originating at a similar ancient time, with a divergence of FtsZ and tubulin from an ancient precursor (Yee *et al.*, 2007). It may be useful to reexamine the phylogenetics of *Prostheco bacter* ftsZs as well as tubulins.

Four-stranded mini-microtubules have been generated by polymerization of cloned purified BtubA and BtubB and share many key structural features with eukaryotic microtubules. These features include a so-called structural 'M-loop' in protofilament protein facilitating contact between protofilaments, alternating BtubA and BtubB subunits, and a seam that breaks overall helical symmetry within the minimicrotubule (Deng *et al.*, 2017).

By means of a special *in vitro* total internal reflection fluorescence microscopy technique, it has been demonstrated that bacterial minimicrotubules display so-called 'treadmilling' (simultaneous lengthening of one end together with shortening of the other end of the microtubule) and also display dynamic instability (switching between phases of growth and phases of shrinking), both distinguishing features of eukaryotic microtubule behaviour (Deng *et al.*, 2017). In dynamic instability in eukaryote microtubules, microtubules switch between phases of growth (lengthening) and shrinking (shortening), and GTP hydrolysis closely follows incorporation of a tubulin dimer into a growing microtubule end (Borisý *et al.*, 2016). Thus, these mini microtubules derived from *Prostheco bacter* tubulins seem to display functional as well as structural homologies with eukaryote microtubules, despite their relative simplicity.

The discovery of *Prostheco bacter* tubulins has led to deep investigation of these proteins both experimentally concerning their ability to form polymers and the properties of such polymers, and structurally regarding how similar the components critical for polymer formation by the Btub tubulins are to the analogous components of eukaryote tubulin structures. BtubA and BtubB have been claimed to form tubes containing 5 protofilaments and these can be demonstrated in three *Prostheco bacter* species inside cells imaged via cryoelectron microscopy (Fig. 3), apparently associated with the *Prostheco bacter* cell stalk region or connection of stalk with the rest of the cell (Pilhofer *et al.*, 2011). Another study on BtubA/B polymerization *in vitro* found formation of 4-filament tubes (Deng *et al.*, 2017).

In the initial study describing tubulins in *Prostheco bacter dejongei*, it was also noted that a gene for a homolog of the light chain of the eukaryote protein kinesin, a microtubule motor protein, was the next open reading frame downstream of the BtubB tubulin gene in the genome (Jenkins *et al.*, 2002). The Btub genes and this kinesin homolog gene form an operon the genomic environments of which have been argued to support the concept of horizontal gene transfer origin of the operon genes (Pilhofer *et al.*, 2007a). The protein contains a TPR domain but has been proposed to differ in function from a eukaryote kinesin. That this *bklc* gene and its cognate protein Bklc (also called BtubC) (also known as "bacterial kinesin light chain") may be of functional significance to *Prostheco bacter* cell biology is indicated by the discovery that BtubC binds along BtubAB protofilaments at regular 8 nm intervals, inhibits BtubAB depolymerization or "mini microtubule catastrophe", and increases protofilament 'rescue' (Deng *et al.*, 2017) and by the discovery that Bklc (BtubC) interacts specifically not only with Btub protofilaments but also with lipid

Fig. 3 Electron microscopy/cryotomography of cytoskeletal microtubule-like structures imaged in sliced frozen cells of *Prostheco bacter vanneervanii* cells showing tube-like BtubA/B-candidate structures occurring (A) individually or (B) in a bundle, from 11-nm thick slices through cryotomograms. Arrows indicate cytoskeletal structures, which are also shown enlarged below. Asterisk in panel A identifies a sub-tomographic average. Upper-left insets show low-magnification overviews of the cells; rectangles indicate areas imaged in 3-D. Bottom: 3-D segmentation of the bundle of panel B shown from two views (four tubes are present). Scale bars are 100 nm. From Fig. 1 in Pilhofer *et al.*, 2011.

vesicles, (Akendengue et al., 2017) and could thus play a role in anchoring BtubAB filaments to membrane protrusions in *Prostheco bacter*. In the eukaryote cytoskeleton cell biology kinesin is a protein linking vesicle-packaged cargo to microtubules, so a role for kinesin in binding to tubulin protofilaments could suggest a possible precursor stage in evolution of more advanced microtubule function (Akendengue et al., 2017). It is conceivable that tubulins of *Prostheco bacter* perform a function connected with cell division, membrane-attached chromosome segregation or transport of membranes or macromolecules inside the cell, if not with stalk formation as such (since stalks form in cells of *btubAB*-less *P. fluvialis*), but in any case these tubulins and their polymerized mini-microtubules appear to display *in vitro* properties remarkably analogous to those of eukaryotic tubules and their polymers.

Relevant to the possible more widespread occurrence of tubulins in verrucomicrobia is the discovery in verrucomicrobial epixenosome symbionts of protozoans (referred to above) of tubules which are sensitive to nocodazole, an inhibitor of eukaryotic tubulin polymerization, and which react positively with antibodies against eukaryotic tubulins (Petroni et al., 2000). There is not yet genome data indicating homology of any tubulin genes of epixenosomes to eukaryote tubulins. Wider occurrence of tubulins in distinct verrucomicrobial genera would be consistent with the concept of their presence in ancestral verrucomicrobia.

Membrane-Coat (MC) Proteins

Another feature analogous to eukaryotes present in verrucomicrobia is the occurrence of so-called membrane-coat proteins homologous to those in eukaryotes such as the clathrins involved in coated pit formation central to the eukaryote-characteristic process of macromolecule uptake called endocytosis (Santarella-Mellwig et al., 2010).

For example, there are 16, 14, and 9 MC-like protein genes respectively in the genomes of verrucomicrobia of 3 different subdivisions, *Verrucomicrobium spinosum* (subdivision 1) *Chthoniobacter flavus* (subdivision 2) and *Pedospaera parvula* strain Ellin514 (subdivision 3) (Kant et al., 2011; Santarella-Mellwig et al., 2010). In addition to their occurrence in such verrucomicrobia, these homologs are also found in related PVC phyla *Planctomycetes* and *Lentisphaerae*, but appear to be quite rare among bacterial genomes as a whole (Santarella-Mellwig et al., 2010). The presence of such eukaryote-like proteins is consistent with the presence of internal membrane complexity and potential compartments in planctomycetes and verrucomicrobia, and may be correlated with an endocytosis-like ability to uptake proteins from the external milieu by the planctomycete *Gemmata obscuriglobus* (Lonhienne et al., 2010).

Conclusion/Summary

The phylum Verrucomicrobia is an excellent example of how a divergent group of bacteria can significantly enrich our understanding of the contributions of microorganisms to the ecosystem, to human health, and to understanding evolution of cell biology among divergent forms of cell organization. Before their discovery we had no knowledge of the contribution of this phylum to the gut microbiome, to the soil microbial community, or to the evolution of different forms of cytoskeletal proteins potentially linking ancestors of bacteria and eukaryotes. *Akkermansia muciniphila* may in the future form an important contribution to human medicine and public health, and *Prostheco bacter* species and their tubulin proteins may supply significant insights into the functioning of microtubules within even human cells. Understanding contributions of verrucomicrobia to plant and soil function is important for improved agriculture and understanding of global terrestrial ecosystems. And finally, understanding the full implications of the relationships of verrucomicrobia to related phyla such as *Planctomycetes* and the medically significant *Chlamydiae* may open up new fundamental fields of evolutionary microbiology relevant to understanding cell complexity and how diverse bacterial life cycles have evolved.

Glossary

Clone library Heterogeneous collection of cloned sequences (often 18S rDNA) derived from a complex assemblage of organisms.

Ecophysiology Physiological properties explaining the ecological adaptation of an organism.

Ecotypes Species varieties with indistinguishable morphology adapted to slightly different ecological niches. Genetic markers can be used to tell them apart.

Environmental molecular surveys Retrieval of genetic signatures from a complex microbial assemblage for diversity studies.

Epifluorescence microscopy Technique that allows observation by fluorescence of very small cells retained on a filter.

Fluorescent in situ hybridization (FISH) Microscopic method for detection of microbial cells by labeling them with a fluorescent probe that specifically labels ribosomes.

High throughput sequencing An emergent set of tools that can produce a huge amount of sequences from several samples at once.

Marine alveolates (MALV) Novel clades that belong to the eukaryote supergroup alveolates, detected in molecular surveys of marine picoplankton.

Marine stramenopiles (MAST) Novel clades that belong to the eukaryote supergroup stramenopiles, detected in molecular surveys of marine picoplankton.

Microbial loop Conceptual scheme stating that a fraction of primary production is released as dissolved organic matter (DOM) and channelized to higher trophic levels through heterotrophic bacteria and protists.

Phylogenetic clade Set of related sequences that originate from a single common ancestor.

Phylogenetics Study of the evolutionary relationships among a set of genes or organisms based on comparisons among a set of shared characters.

Picoplankton Heterogeneous assemblage of organisms $\leq 2\text{--}3\text{ }\mu\text{m}$ in size that live suspended in the water column.

Protists General term for eukaryotes not belonging to plants, animals, fungi, or macroalgae, generally single-celled organisms of sizes from $1\text{ }\mu\text{m}$ to more than $100\text{ }\mu\text{m}$.

Single cell genomics Retrieval of the genome sequence from an individual microbial cell.

18S rDNA Gene encoding the RNA component of the small ribosomal subunit, and widely used to identify and classify organisms.

Defining Statement

Microorganisms play fundamental roles in marine ecosystems, sustaining food webs and driving biogeochemical cycles. Unicellular eukaryotes smaller than 2–3 μm (picoeukaryotes) are recognized as important members of microbial assemblages in terms of both biomass and activity. They show a large functional and phylogenetic diversity and include many poorly or entirely uncharacterized taxa.

Introduction

What Are Marine Picoeukaryotes?

Marine picoeukaryotes are a heterogeneous assemblage of very small eukaryotic organisms. Although some examples of cultured picoeukaryotes exist, most have only been detected in the last decade using culture-independent sampling techniques and therefore have been poorly characterized. Nonetheless, we now know that picoeukaryotes are ubiquitous throughout the marine environment, occupying a wide variety of habitats. This includes distinct layers of the water column, each with its own dominant biogeochemical regime, marine sediments, and unique ecosystems such as hydrothermal vents.

Salinity is the main parameter that differentiates marine and freshwater habitats, and these habitats are for the most part populated by very different species. Little is yet known about picoeukaryotes in freshwater habitats. Therefore, this article will focus on planktonic marine picoeukaryotes, those that live suspended in the water column, and especially those living in the upper water column where photosynthesis occurs. Since most primary production in marine systems is due to photosynthesis by planktonic microorganisms (cells smaller than 200 μm), the microbial component plays a key role in marine food webs. Among these organisms, picoeukaryotes, many of which have only recently been discovered, are qualitatively and quantitatively important. Marine primary production accounts for roughly half of the Earth's production, indicating that the oceans and their microorganisms are crucial in sequestering inorganic carbon from the atmosphere and potentially in mitigating global change.

Picoeukaryotes have a typical eukaryotic cell structure in a miniaturized state. This includes the presence of a nucleus, an endomembrane system (endoplasmic reticulum, Golgi body, and vesicles), mitochondria, and in the case of photosynthetic picoeukaryotes, a chloroplast. Nonetheless, these cells are extremely small, the diameter ranging from 0.8 μm in the case of *Ostreococcus tauri*, the smallest known eukaryote, to an upper range of 2–3 μm . Due to this small size, picoeukaryotes are largely indistinguishable by light microscopy, the usual method for studying eukaryotic microbial diversity. In addition, few picoeukaryotes have been isolated and characterized.

In 1978 a scheme for classification of marine organisms according to size was delineated largely based on sieving technology. Microorganisms were operationally split into three categories: picoplankton (0.2–2 μm in cell diameter), nanoplankton (2–20 μm), and microplankton (20–200 μm). Initially, the picoplankton was thought to be almost exclusively made up of prokaryotes and the nanoplankton mostly of small single-celled eukaryotes. However, the existence and abundance of protists within the picoplankton size class was soon recognized. Today, the term picoeukaryotes is often used a bit loosely to include protists with a size up to 3 μm . Direct inspections of protist assemblages indicate that the 2 μm limit often falls in the middle of the size spectra and that a more coherent group is delimited using a 3 μm upper boundary.

Picoeukaryotes thus defined (protists smaller than 3 μm) are abundant in the marine plankton. They include diverse phototrophic and heterotrophic cells, and they play crucial roles as primary producers, bacterial grazers, and parasites. In recent years their diversity, abundance, and widespread distribution has begun to be recognized and they are attracting more attention.

Method-Driven History of Marine Picoeukaryotes

Microorganisms are invisible to the unaided human eye, so the history of their study is inevitably linked to the development of new methods for their observation and characterization (Fig. 1). The existence of very small cells in the marine plankton was known from the beginning of the 20th century by phytoplanktologists that inspected concentrated samples of seawater by light microscopy. By the middle of the century the first picoeukaryotes, such as the flagellated *Micromonas pusilla* (formerly, *Chromulina pusilla*), were obtained in pure culture. This and other cultured picoeukaryotes provided the basis for many early microscopic and physiological studies, leading to the description of new species. The easy cultivability of *M. pusilla* allowed the initial estimations of its abundance by the serial dilution method. This showed that it is widely distributed in the marine environment and can reach abundances as high as 10^4 cells mL^{-1} . Despite this particular success with cultured organisms, microbial ecologists soon became aware that the dominant microorganisms were often not easily cultured, so direct inspections of natural samples and culture-independent approaches were still much needed.

Electron microscopy, which had been used on cultured material since the 1950s, started to be applied to inspect natural protist assemblages during the 1970s. Transmission electron microscopy (TEM), which allows the inspection of intact specimens, revealed conspicuous features of nanoplanktonic protists. However, these studies rarely targeted picoeukaryotes. The latter were first detected by TEM in thin sections of centrifuged natural samples in 1982. *M. pusilla* and an unknown prasinophyte (later identified as *Bathycoccus prasinos*) were seen in many coastal and oceanic samples, sometimes being relatively abundant. These observations also

provided the first clue on mortality of picoeukaryotes, since cells often appeared infected with large viruses. Soon after this study, it was shown that a large fraction of marine primary production in offshore regions is due to picophytoplankton (cyanobacteria and picoeukaryotes).

The first accurate counts of marine picoplankton were obtained by epifluorescence microscopy in the early 1980s. This was based on the fluorescence (natural or stain induced) emitted by cells retained quantitatively on the surface of flat polycarbonate filters. Bacterial numbers revealed by this approach were orders of magnitude higher than deduced from previous cultivation-dependent techniques. Protists of different sizes were also evident at abundances in the thousands of cells per milliliter. In addition, phototrophic or heterotrophic protists, which play fundamentally different ecological roles, could be counted separately based on the presence or absence of chlorophyll autofluorescence. Epifluorescence microscopy still remains the method of choice (albeit

time-consuming) for counting heterotrophic picoeukaryotes (HP). Phototrophic picoeukaryotes (PP), on the other hand, can be more easily counted by flow cytometry, a technique imported from biomedicine based on the laser detection of single cells flowing through a small aperture. Flow cytometry was first applied to marine ecology in the 1980s, and was instrumental in the discovery of the most abundant phototroph on Earth, the cyanobacterium *Prochlorococcus*. This tool has been extensively applied to describe the global distribution of marine PP.

The 21st century started with a fair knowledge of the global abundance and distribution of marine picoeukaryotes in the sea and a sizeable collection of characterized cultures. However, there was a remarkable lack of knowledge about which species dominate natural assemblages, and whether or not the cultured strains represented relevant ecological models. This was because the techniques used for identification (culturing, electron microscopy) were not quantitative, and conversely the techniques used for quantification (epifluorescence microscopy, flow cytometry) did not permit species identification.

This changed radically with the advent of molecular tools, particularly culture-independent sampling of ribosomal RNA sequences (phylotypes) from selected environments. These provided exciting and novel results for marine bacteria and archaea during the 1990s, revealing whole new phyla and possibly even kingdoms of organisms. The first studies on the in situ diversity of marine picoeukaryotes by cloning and sequencing environmental 18S rRNA genes were published in 2001. Similar to studies of marine prokaryotes, these revealed new major groups of eukaryotes. Later, specific phylogenetic groups were targeted by fluorescent in situ hybridization (FISH), which allows for directly observing and quantifying natural cells in the environment. The FISH approach was particularly successful for organismal lineages seen in clone libraries but with no known close relative in culture. The use of molecular tools has revealed an unexpected diversity of protists, including the presence of novel groups, suggesting that marine picoeukaryotes represent a large reservoir of unexplored biodiversity. Recently, the implementation of HTS (high-throughput sequencing) tools on large sampling datasets, and on individual cells through SCG (single cell genomics), is providing a new impetus on studies of the ecological and evolutionary significance of picoeukaryotes.

Biology of Cultured Marine Picoeukaryotes

Cultured Strains

Marine picoeukaryotes have been isolated using standard methods, such as mineral media and light for phototrophic cells and rice (or yeast extract) enrichment media for heterotrophic cells, often inoculated with 2–3 μm filtered seawater. To describe a new species, isolates must be characterized by a set of complementary techniques. Optical microscopy reveals the cell shape and motility pattern. Electron microscopy uncovers the cell ultrastructure: architecture of mitochondria, chloroplast, and flagellar apparatus, number, size, and ornamentation of flagella, and presence of external structures. Molecular markers, mostly 18S rDNA but also other genes, allow for phylogenetic placement of new isolates. Biochemical markers, such as pigment analysis by high-performance liquid chromatography (HPLC), storage products, or fatty acid profiles also provide specific information. A subset of these techniques may be used to assign new isolates to a given species, but molecular markers are used most commonly because they are faster and easier to gather. Once formally described, strains are deposited in culture collections, such as the National Center for Marine Algae and Microbiota (formerly the CCMP) in the United States or the Roscoff Culture Collection in France.

Since the first culture of *M. pusilla* was isolated in 1952, there has been some success in isolating additional picoeukaryotes (Table 1). Most are phototrophic and belong to the green algae and the stramenopiles. Cultured green algal picoeukaryotes belong mostly to the class Mamiellophyceae (*Micromonas*, *Ostreococcus*, and *Bathycoccus*), although Pedinophyceae and Trebouxiophyceae also contain small cells. Stramenopile picoeukaryote cultures all belong to novel algal classes, such as Pelagophyceae (1993), Bolidophyceae (1999), and Pinguiophyceae (2002), described recently. The only example of a cultured picophytoeukaryote besides these two divisions is the cryptophyte *Hillea marina*, although this species is still not well characterized.

There are few HP in culture, and most belong to the chrysomonads or the bicosoecids. This scarcity probably reflects the difficulty of isolating and maintaining heterotrophic protists, which usually requires culturing with prey, typically bacteria in the case of phagotrophic picoeukaryotes. A promising approach involves trying to recreate natural conditions during the isolation, by directly adding previously concentrated natural bacteria. This approach has led to the isolation of the rhizarian *Minorisa minuta*. In addition, there are parasitic protists that release very small heterotrophic cells as free-living dispersal zoospores and can only be maintained in culture with their specific host. For instance, some strains of the alveolates *Amoebophrya* and *Parvilucifera*, parasites of marine dinoflagellates, have zoospores as small as 3 μm .

In addition, some larger cultured species have a minimal cell dimension $\leq 3 \mu\text{m}$. These are not strictly picoeukaryotes but would pass through the 3 μm pore size prefilter used to fractionate picoeukaryotes in environmental surveys. Phototrophic species of this size category belong to all classes with picoeukaryotes shown in Table 1 as well as Prymnesiophyceae and some additional stramenopiles (e.g., Bacillariophyceae, Dictyochophyceae, and Eustigmatophyceae). Some of these, such as the Bacillariophyceae (diatoms) and the Prymnesiophyceae, include very important marine phytoplankters. Additional heterotrophic species span the breadth of the eukaryotic tree including cercomonads (supergroup Rhizaria), kinetoplastids and jakobids (supergroup Excavates), choanoflagellates (supergroup Opisthokonts), and apusomonads (unclear affiliation).

Some picoeukaryotic species have been named based on direct observations of natural samples, enrichments, or temporary cultures. Examples are the heterotrophic flagellate *Pseudobodo minimum* (a bicosoecid 2.0 μm in size) and the green alga *Chlorella minima* (1.5–3 μm). Morphological descriptions can be accompanied by ultrastructural characters obtained by electron microscopy,

Table 1 Some examples of marine picoeukaryotes in culture, including the cell size (minimal and maximal length), trophic mode, and where the culture is deposited

Taxonomic group	Species	Size (μm)	Trophic	Culture collection
Green algae				
Pedinophyceae	<i>Marsupiomonas pelliculata</i>	3.0–3.0	P	PCC
	<i>Resultor micron</i>	1.5–2.5	P	SCCAP
Mamiellophyceae	<i>Bathycoccus prasinos</i>	1.5–2.5	P	RCC, NCMA
	<i>Dolichomastix lepidota</i>	2.5–2.5	P	
	<i>Micromonas pusilla</i>	1.0–3.0	P	RCC, NCMA
	<i>Ostreococcus tauri</i>	0.8–1.1	P	RCC, NCMA
Prasinophyceae	<i>Picocystis salinarum</i>	2.0–3.0	P	RCC, NCMA
Trebouxiophyceae	<i>Chlorella</i> sp.	2.0–3.0	P	RCC
	<i>Picochlorum eukaryotum</i>	3.0–3.0	P	RCC, NCMA
Cryptophyta				
Cryptophyceae	<i>Hillea marina</i>	2.0–2.5	P	
Stramenopiles				
Bicosoecida	<i>Caecitellus pseudoparvulus</i>	2.0–3.0	H	RCC
	<i>Cafeteria roenbergensis</i>	3.0–3.0	H	RCC
	<i>Symbiomonas scintillans</i>	1.2–1.5	H	RCC, NCMA
	<i>Bolidomonas pacifica</i>	1.0–1.7	P	RCC, NCMA
Bolidophyceae	<i>Triparma laevis</i>	2.0–3.0	H	RCC,
	<i>Picophagus flagellatus</i>	1.4–2.5	H	RCC, NCMA
Chrysophyceae	<i>Aureococcus anophagefferens</i>	1.5–2.0	P	RCC, NCMA
Pelagophyceae	<i>Pelagomonas calceolata</i>	2.0–3.0	P	RCC, NCMA
	<i>Pinguiochrysis pyriformis</i>	1.0–3.0	P	RCC, MBIC
Rhizaria				
Chlorarachniophyceae	<i>Minoria minuta</i>	1.0–3.0	H

such as for the cercozoan *Phagomyxa odontellae* (a diatom parasite with zoospores of $3\text{--}4 \times 2\text{--}3 \mu\text{m}$) or the Parmales. The latter was an intriguing algal group, commonly observed in the sea thanks to their covering by siliceous plates. Although initially classified within the class Chrysophyceae, a few parmales species have been recently isolated and phylogenetically placed within the class Bolidophyceae.

Cellular Organization

Marine picoeukaryotes are miniaturized unicellular organisms that nonetheless retain all typical eukaryotic subcellular structures. They mostly divide asexually, a common feature in many protists, and a complete life cycle with the presence of a sexual phase is presumed, yet generally uncharacterized. The algal class with most cultured picoeukaryote species is the Mamiellophyceae. These cells have a single chloroplast (often with a starch granule) with chlorophyll b and prasinoxanthin as the main accessory pigments, one mitochondrion, and one Golgi body. The three most common cultured genera illustrate the variability within the class. *B. prasinos* lacks flagella and is covered by spider web-like organic scales. *M. pusilla* is naked, has a single flagellum with a short wide base and long thin distal end and a distinct characteristic swimming behavior. *O. tauri* is coccoid, nonmotile, and naked. For each of these, strains with indistinguishable ultrastructural features have been isolated from distant geographic sites. For *B. prasinos* these strains appear to be genetically similar, but there is a clear genetic structure among *M. pusilla* (at least five clades) and *O. tauri* (at least four clades) strains. It has been proposed that these clades can be viewed as ecotypes with specific adaptations to their environments (see later). The remaining picoeukaryotic green algal species show similar minimal cell structure but have different flagellar architecture, pigment signatures, and swimming behavior.

The second group with a significant number of cultured picoeukaryote strains is the stramenopiles. This is a vast and extremely diverse clade of autotrophic and heterotrophic taxa, most of which have two unequal flagella, the longer being covered by tripartite hairs that reverse the thrust from the flagellum. Photosynthetic stramenopiles have chlorophyll c as the main accessory pigment and the chloroplast is surrounded by an endoplasmic reticulum continuous with the outer nuclear membrane. Picostramenopiles have a simplified cell structure, with a single mitochondrion, one chloroplast, and one Golgi body. *P. calceolata* is covered by a thin organic theca and has only one flagellum with two rows of bipartite hairs, and even lacks the basal body of the second flagellum. Its main carotenoid is 19'-butanoxylfucoxanthin. *Bolidomonas pacifica* is naked and has two unequal flagella, the longer with tubular hairs similar to those of *P. calceolata*. It can swim vigorously, up to 1.5 mm per second, and contain fucoxanthin as the main carotenoid, like diatoms. Within the same class, *Triparma laevis* share some cell features and

pigment composition with *Bolidomonas* spp., but also differ considerably by virtue of being unmotile cells covered by silica plates. *Pinguiochrysis pyriformis* is coccoid, naked, lacks flagella, and produces large amounts of polyunsaturated omega-3 fatty acids. HP within the stramenopiles also have a simplified cell structure, with a nucleus, a single Golgi body, 1–2 mitochondria, and no chloroplast. *S. scintillans* is naked and has a single flagellum (and only one basal body) with two rows of tripartite tubular hairs. It contains several endosymbiotic bacteria located close to the nucleus. *P. flagellatus* is naked, has two unequal flagella, the longer with two rows of tripartite hairs, and swims energetically.

Physiological Parameters

Cultured picoeukaryotes provide necessary material not only for ultrastructural, biochemical, and molecular studies, but also for defining physiological properties. Some physiological parameters deal with how fast unicellular organisms use environmental resources, such as inorganic nutrients and light for phototrophs and prey for phagotrophs. For instance, the functional response of a phagotrophic protist relates the ingestion rate with prey availability: at low prey levels, the ingestion rate increases linearly with prey concentration; at medium levels, the rate still increases but not linearly; and at high levels, the rate reaches a maximum. This relationship can be described by several models. The most commonly used is analogous to the Michaelis–Menten equation for enzyme kinetics, which is based on the maximal ingestion rate (U_m) and the prey concentration allowing half U_m (K_m). Both parameters are characteristic of a given species and have interesting ecological implications: U_m gives the upper limit of a species grazing capacity and K_m roughly indicates the prey concentration at which the species is adapted to live. The uptake of inorganic nutrients by a phototroph can be described by the same equation. The relationship between light and photosynthetic activity, on the other hand, uses a different model to incorporate the inhibitory effect of high irradiances.

The differential use of resources translates into different growth rates. In the case of phagotrophic protists, a similar relationship can be found between prey availability and growth rate, known as numerical response, again modeled by the Michaelis–Menten equation. A crucial parameter for phagotrophs is growth efficiency, the fraction of the food ingested that is converted to biomass. This relates ingestion rates and growth rates and has strong implications for respiration and nutrient remineralization. For phototrophic protists, growth rate is often the activity parameter measured to follow their relationship with inorganic nutrients and light. The plasticity with which protists change their reproductive rates according to the available resources is remarkable.

This simplistic view of resource–activity relationships becomes more complex when taking into account the properties of given resources, providing an additional set of more realistic species-specific physiological parameters. In photosynthetic protists, the quality of light and the chemical state of inorganic nutrients can be important. Accessory pigments can tune the cell to a given region of the light spectrum, whereas membrane transporters, genetically codified, determine the nutrient state that can be used. Heterotrophic protists can choose prey depending on size, phylogenetic composition, surface properties, and motility behavior. Finally, there are other species-specific responses related to environmental parameters, such as temperature. Altogether, physiological parameters for a given species may explain its competitive advantage and success in the environment. Conceptual models illustrating how variations in these parameters may induce similar species (or ecotypes of the same species) to occupy different ecological niches are shown in Fig. 2.

O. tauri represents a good example of ecotype differentiation. Twelve *O. tauri* strains are ultrastructurally indistinguishable but form distinct genetic clades using rDNA sequences. One clade is formed by strains isolated from the bottom of the photic zone (~100 m deep), which grow well at low irradiances but are inhibited at irradiances typical of surface waters. The clade formed by strains isolated from surface waters, on the other hand, represents a high-light-adapted ecotype only growing at surface irradiances. The low-light ecotypes possess additional photosynthetic pigments absent from high-light ecotypes. These different ecotypes, which together are able to exploit a wide range of light levels, might explain the success of *O. tauri* throughout the photic zone. Ecotype differentiation has also been observed in *M. pusilla*, where strains of one clade seem to be adapted to live in polar waters. It is plausible that ecotype diversity is a widespread phenomenon in the microbial world.

The Implications of Being Small

Cell size is the single trait that most influences the physiological and ecological properties of a given organism. Smaller cells, by virtue of their higher surface-to-volume ratio as compared to larger cells, are generally more efficient in resource acquisition and therefore may have higher specific metabolic rates. Very crudely, physiological rates are inversely proportional to body length, the so-called allometric relationship. Thus, picoeukaryotes would be the protists with the highest growth rates and better adapted to oligotrophic conditions. Picoeukaryotes live in an environment with low Reynolds numbers, where their motility is dominated by viscous forces and inertial forces are negligible. This implies that all movements have to be active and that cells do not sink passively. Finally, from an ecological perspective, cell size is the best indicator of the level an organism occupies in the trophic food web. Although there are many exceptions, phagotrophs eat organisms smaller than themselves with a general predator-to-prey ratio of 10:1 (length). So, picoeukaryotes would always be near the base of food webs, and their biomass would arrive at macroscopic trophic levels only after several trophic transfers.

Fig. 2 Conceptual models illustrating how physiological responses induce ecological adaptation. (a) The low-adapted phototrophic ecotype grows better at low irradiances, and the high-adapted ecotype at high irradiances. (b) The oligotroph phagotrophic ecotype grows better at low prey concentration and the copiotroph at high levels. (c) The psychrophilic ecotype grows better at cold temperatures and the mesophilic ecotype at warmer temperatures.

Picoeukaryotes in the Marine Environment

Bulk Abundance and Distribution

Very small protists are found in essentially all seawater samples inspected by epifluorescence microscopy. Since these protists were considered nanoplanktonic and flagellated, they are routinely referred to as phototrophic nanoflagellates (PNF) if they contain chlorophyll, and heterotrophic nanoflagellates (HNF) if they are colorless. However, few cells are larger than 5 μm and many are $\leq 2 \mu\text{m}$. A recent effort in protist counting and sizing by epifluorescence in contrasting marine systems reveals that 84% of phototrophic protists (between 75 and 91% depending on the system), and 76% of heterotrophic protists (between 64 and 84%) are 3 μm or smaller. So, most PNF and HNF cells would qualify as picoeukaryotes in all marine habitats studied. It should be noted that, due to the absence of flagella in some picophytoeukaryotes, the terms PP and HP are probably more appropriate when referring to the epifluorescence counts of small protists.

There is an extensive database on epifluorescence counts of marine PP and HP. These operationally defined groups are ubiquitous throughout the photic zone at concentrations of thousands of cells per milliliter. PP are generally the most abundant picoeukaryotes and show a large variability, with cell counts typically increasing with the trophic status of the sample. Conversely, HP are several times less abundant than PP but vary only moderately across systems, generally less than one order of magnitude, and are often correlated with bacterial abundance. In coastal systems, typical ranges for PP are $1.1\text{--}8.5 \times 10^3 \text{ cells mL}^{-1}$, with episodic peaks well above $10^4 \text{ cells mL}^{-1}$, whereas HP concentrations typically vary between 0.6 and $3.1 \times 10^3 \text{ cells mL}^{-1}$. Cells are less abundant in offshore, more oligotrophic systems: typical PP concentration ranges from 1.0 to $3.3 \times 10^3 \text{ cells mL}^{-1}$ and HP ranges from 0.6 to $1.5 \times 10^3 \text{ cells mL}^{-1}$. For example, in offshore Indian Ocean samples, average cell counts were $1.7 \times 10^3 \text{ cells mL}^{-1}$ for PP and $0.45 \times 10^3 \text{ cells mL}^{-1}$ for HP. The ubiquity, abundance, and constancy of picoeukaryotes suggest they are important players in the photic zone and that their growth and mortality rates are tightly coupled.

Understanding of the patterns of PP distribution has been considerably expanded by the semiautomatic counts provided by flow cytometry. Inspection of marine samples by this technique reveals an assemblage of photosynthetic picoeukaryotes, generally at thousands of cells per milliliter, yielding counts consistent with those of PP counted manually by epifluorescence. Flow cytometry is routinely used in oceanographic cruises and monitoring programs and allows direct comparisons of picophytoplankton groups.

Results indicate that PP generally covary with *Synechococcus* and dominate in coastal waters, whereas these protists are less abundant offshore where *Prochlorococcus* dominates. Flow cytometry has also been used to quantify HP cells, but the current approach provides data that is too noisy (large prokaryotes can be counted as HP), so this is not yet a standard tool in oceanography.

Photosynthesis does not occur below the photic zone, in the mesopelagic (200–1000 m deep) and bathypelagic (1000–4000 m) regions; so this extensive biome is largely devoid of photosynthetic protists. Nevertheless, bacterial production can occur in these deep waters based on sedimenting organic matter from the photic zone and on chemolithoautotrophic bacteria gathering their energy from reduced inorganic compounds. However, both bacterial abundance and production is still 1–2 order of magnitude lower here than at the surface, and the numbers of heterotrophic picoeukaryotes as seen by epifluorescence microscopy are also lower, ranging between 10 and 100 cells mL⁻¹.

Ecological Role of PP

It has long been known that microorganisms are responsible for most of the marine primary production. However, prior to 1983 we were unaware of the importance of picoplankton in this crucial process. Picophytoplankton generally dominate primary production in offshore, oligotrophic systems, and can also be important in coastal systems on a seasonal basis. For instance, picoplankton averaged 71% of photosynthetic biomass and 56% of primary production during four Atlantic Ocean cruises (50 degree N–50 degree S) crossing coastal, upwelling, and central oceanic regions. Picocyanobacteria, specifically *Synechococcus* in nutrient-rich and *Prochlorococcus* in oligotrophic regions, can reach abundances of up to 10⁵ cells mL⁻¹, so they were initially thought more important in supporting food webs than picoeukaryotes. However, albeit less abundant, picoeukaryotes are larger (their biovolume can be 100 times that of picocyanobacteria), so they can contribute significantly to primary production. For example, a study in the central North Atlantic indicated that while only 10% of the surface picoplankton were eukaryotes, these contributed 61% of the biomass and 68% of the primary production.

The size spectrum of marine primary producers strongly influences the food web complexity and has crucial implications for transfer efficiency to higher trophic levels. Large cells such as diatoms and large dinoflagellates can be readily consumed by copepods and directly sustain fish larvae. However, primary production based on very small cells has to pass through several trophic steps (flagellates, ciliates) and a significant fraction of this organic matter is respired at these lower levels. Thus, even though picoeukaryotes appear to be optimal food for small predators, systems largely reliant on their production are less efficient in sustaining higher trophic levels. Other mechanisms, such as viral lysis, also potentially diminish trophic efficiency by causing direct remineralization of picoeukaryotic biomass. The role of viruses as mortality agents in picoeukaryotes (and other algae) remains poorly explored.

The magnitude of the ocean's biological pump (sequestration of atmospheric inorganic carbon to the deep ocean by biological export) is also considered to be heavily influenced by the cell size and species composition of phytoplankton. That is, larger cells are expected to contribute more to inorganic carbon sequestration. This is because larger cells, often with mineralized structures, can sediment directly (alone or in aggregates) or be readily consumed by copepods that excrete fecal pellets that sink out of the surface mixed layer. However, recent data suggest that picoplankton may also contribute to carbon export from the surface at a level proportional to its net primary production.

Ecological Role of HP

HP are mostly phagotrophs and are central in the microbial loop, a concept that has driven a fundamental revision of models of marine food webs. The microbial loop is based on the premise that there is a substantial supply of dissolved organic matter (DOM) created by phytoplankton exudation or inefficient zooplankton feeding that supports active bacterial production. These active bacteria are grazed upon by small protists that in turn are food for larger grazers. So, incorporated into the classical food web (phytoplankton, copepods), there is a microbial loop (DOM, small grazers, copepods) that potentially transfers energy from dissolved pools to higher trophic levels. The reality is closer to a web than a loop, since small grazers also consume picophytoplankton, often the dominant producers. The main grazers of bacteria and picophytoplankton are picoeukaryotes, as seen by microscopic inspections of protists with ingested bacteria and by size fractionation experiments showing that most bacterial grazing occurs in the fraction below 3 µm.

Grazing by HP represents an important mortality factor for bacterial assemblages over large oceanic scales. Other mortality agents like viruses may contribute in coastal systems but seem less important in oligotrophic regions. Mixotrophic protists, cells capable of both phagotrophy and photosynthesis, can contribute to half of bacterial mortality in both coastal and offshore systems. Bacterial grazing, by either heterotrophic or mixotrophic protists, is the first of a multistep food chain, during which bacterial production is mostly respired and inorganic nutrients bound to bacterial biomass (often enriched in P and N) are released. Thus, the main ecological roles of phagotrophic picoeukaryotes are controlling bacterial (and other picoplankton) abundances and remineralizing inorganic nutrients in the photic zone, allowing sustained primary production in oligotrophic systems.

HP may have other nutritional modes besides phagotrophy. Strictly osmotrophic protists are generally poor competitors to heterotrophic bacteria, which seem more efficient in using the diluted and refractory marine DOM. Nevertheless, there may be particular habitats (enriched coastal sites, the deep ocean) where eukaryotic osmotrophs may make a living. Also, the existence of

phagotrophic protists that can supplement their diet with DOM is plausible and ecologically relevant. Parasitism has long been known to occur in the sea, and there are many descriptions of parasites infecting protists (e.g., diatoms, dinoflagellates) and metazoans (e.g., copepods, crabs). These parasites always have a free-living dispersal form (zoospore), colorless and often very small, which would be considered as HP. Parasitism is fundamentally different from phagotrophy because the parasite is typically much smaller than the host, has a limited host range, and does not always kill its host. Given the high diversity of microbial assemblages and the dilute environment in which they live, parasitism was not considered as a major process in the marine plankton. However, recent environmental molecular surveys (see [Section In Situ Phylogenetic Diversity](#)) reveal many sequences of putatively parasitic protists retrieved from the picoplankton, even at the more oligotrophic stations studied. The ecological relevance of parasitism in coastal and offshore microbial assemblages is an open field for future research.

Molecular Tools to Study Picoeukaryote Ecology

Elusive View of In Situ Diversity by Nonmolecular Tools

Despite the ecological importance of picoeukaryotes as primary producers, bacterial grazers, and parasites, it is remarkable how little we knew about in situ diversity before the application of molecular tools. This is because picoeukaryotes cannot be identified by the techniques that provide accurate cell counts, such as epifluorescence microscopy or flow cytometry. Specific ultrastructural features can often be revealed by electron microscopy, but this cannot be applied routinely to all cells of an assemblage, although sometimes it has served to identify dominant species, such as *Micromonas* and *Bathycoccus*.

Culturing is an excellent approach to obtain biological models (see [Section Biology of Cultured Marine Picoeukaryotes](#)). However, many cells do not grow easily in the lab, so culturing provides a severely biased view of microbial diversity. In a few cases, there are dominant populations in the sea that are also easily cultured, so they can be counted by diluting and culturing, yielding a most probable number. An excellent example is the mamiellophyte *M. pusilla*, which is widely distributed in the sea in numbers ranging from 10^2 to 10^5 cells mL^{-1} , being more abundant in coastal areas but also found in the oligotrophic open sea.

Pigment analysis by HPLC yields information on the composition of marine phytoplankton, since each algal group has a specific pigment signature, and has often been used to compare samples during oceanographic cruises. When applied to samples prefiltered through $3\ \mu\text{m}$, it can provide a general view of picophytoplankton composition. Since the pigment profile derives from a complex assemblage, algorithms need to be used to infer the contribution of different algal classes to total chlorophyll *a* (the only pigment common to all phytoplankters). However, translating pigment profiles to diversity depends on the pigment ratios generated in cultured species, which may not accurately represent natural populations, and even then only provides identification to an algal class, not to lower ranks such as genus or species.

Cloning and Sequencing Environmental Genes

Molecular tools were introduced in marine microbial ecology relatively recently. The most widely used gene for these studies is the SSU rDNA, which codes for the small subunit ribosomal RNA (16S rDNA in prokaryotes, 18S rDNA in eukaryotes). This gene has the distinct advantages that it codes for essentially the same function in all organisms, it has both highly conserved and variable regions, and its product (rRNA) is present in many copies in the ribosomes of all living cells. SSU rDNA has been used to delimit the three domains of life and to classify organisms within a given class, genus, and species. The basis of molecular protist ecology is identifying cells in situ by directly retrieving their rDNA. This is achieved by extracting DNA from marine picoplankton assemblages, amplifying the 18S rRNA genes by PCR, cloning and sequencing the PCR products, and comparing the sequences with SSU rDNA databases.

The first culture-independent PCR (ciPCR) studies on marine picoeukaryotes appeared in 2001. These showed that picoeukaryotes are extremely diverse, so the indistinguishable cells seen by epifluorescence hide phylogenetically different organisms. In fact, environmental picoeukaryote sequences are scattered throughout the eukaryotic tree ([Fig. 3](#)). Furthermore, while some of these sequences match well-known species, others form phylogenetic clades (sets of related sequences) that represent novel and unexplored diversity. Studies from widely separated sites often show similar phylogenetic clades, suggesting that few biogeographic barriers exist in the marine realm and similar protists thrive when conditions are similar. Besides 18S rDNA, other genes have been used for similar purposes, such as the chloroplast genes 16S rDNA, *rbcl*, and *psbA*. These target only the phytoplankton, and complement and expand the results obtained with the 18S rDNA.

The cloning and sequencing approach is critical to unveil novel microbial diversity but is severely limited in its ability to reveal the true community composition. First, samples are obtained by sequential filtration (through 3 and $0.2\ \mu\text{m}$ pore size filters), and small cells can break during the process and be lost from the picoplanktonic sample. Organisms larger than $3\ \mu\text{m}$, on the other hand, can break into small fragments or squeeze through pores and be collected as picoplankton. This surely explains the finding of metazoan and ciliate sequences in picoplanktonic clone libraries. Second, some species can be more resistant to DNA extraction than others, depending on their cell structure and outer layers. Third, the required PCR step may bias the original gene abundance, both by primer mismatches and by preferential amplification in some groups. Finally, the rDNA copy number varies widely between eukaryotic species, from one to several thousands, and this surely influences clonal representation. Thus, 18S rDNA clone libraries are fundamental and informative but do not completely describe in situ protist diversity.

Fig. 3 Representation of eukaryotic phylogeny (modified from Baldauf, S.L., 2003. The deep roots of eukaryotes. *Science* 300, 1703–1706). Groups found in picoplankton 18S rDNA libraries are marked with a dot, colored depending its averaged clonal representation: black (>10%), gray (1–10%), and white (<1%).

Beyond Clone Libraries: FISH and Fingerprinting Techniques

After environmental sequencing has identified dominant phylogenetic groups, their abundance and distribution in the sea can be assessed by FISH, a technique that elegantly complements the rRNA approach. FISH also reveals critical features of novel phylogenetic clades such as cell size, thus confirming whether they are picoeukaryotes. During the FISH process, fixed microbial cells immobilized on a filter are hybridized with a taxon-specific 18S rDNA probe labeled with a fluorochrome. So, target cells fluoresce under epifluorescence microscopy. A crucial step in FISH is probe design, the selection of a short DNA sequence (around 20 nucleotides) specific for a given group, be it a species, genus, class, or domain. For probes targeting a novel clade, no culture is available in which to optimize hybridization conditions, so instead a natural sample containing these sequences can be used. Once the FISH protocol is optimized, it is relatively easy to apply, albeit time-consuming. FISH has been successfully used for several groups of marine picoeukaryotes, such as mamiellophytes, stramenopiles, and picozoa. It has provided data on their cell size and abundance, thus giving unambiguous estimates of their contribution to the bulk picoeukaryote assemblage. Presently, the FISH approach is mostly limited by the probes available, so major efforts in probe design and optimization are required.

Fingerprinting techniques are very popular in microbial ecology because they allow a fast comparison of the community composition among samples. They provide a characteristic fingerprint for each sample, typically a banding pattern where each band represents a specific taxa. The most commonly used techniques are denaturing gradient gel electrophoresis (DGGE), terminal-restriction fragment length polymorphism (T-RFLP), and automated ribosomal interspacer analysis (ARISA). All start with a PCR amplification of rDNA genes from the assemblage in question using general primers. Individual sequences in this mixture are then separated by electrophoresis based on their melting domains (DGGE), the location of their first restriction site (T-RFLP), or the size of their ITS region (ARISA). Fingerprinting techniques are used to reveal spatio-temporal patterns of picoeukaryotic assemblages in the sea. Picoeukaryotic assemblages appear to have a relatively wide distribution, with large oceanic areas with similar composition, but they also show significant changes with depth, along onshore–offshore gradients and across frontal regions. Fingerprinting techniques are also very useful to follow the protist dynamics during manipulative experiments.

High-Throughput-Sequencing: A Tsunami of Sequences With Ecological Significance

The technology for massive parallel sequencing has appeared recently and has been applied to many scientific disciplines, including microbial ecology. HTS methods (initially 454 pyrosequencing and, subsequently, Illumina-based systems) allows obtaining thousands to millions of sequences from several samples in the same sequencing run. The big advantage of HTS tools in molecular diversity surveys is the huge number of reads obtained, obviating the time-consuming cloning step needed in Sanger sequencing. On the other hand, the main challenge of HTS is the bioinformatic analysis that is necessary to extract relevant and useful information from these large datasets, with the underlying concept being to group sequences with comparable phylogenetic meaning. So, individual reads are collapsed in OTUs (Operational Taxonomic Units) at a given level of similarity and one sequence is kept as representative of the OTU, which is then classified taxonomically. The resulting OTU table (number of reads of each OTU taxonomically classified in all samples analyzed) will serve to investigate the community structure and alpha diversity of a given sample, how this diversity changes among samples, what are the driving factors for these changes, and other particular aspects as the contribution of novel taxa to community structure or the magnitude and significance of the rare biosphere.

In Situ Phylogenetic Diversity

Overview of 18S rDNA Sequences From Marine Picoeukaryotic Communities

The phylogenetic diversity contained within marine picoeukaryotes is astonishing, as the majority of eukaryotic lineages are represented in 18S rDNA molecular surveys (Fig. 3). Some of the retrieved sequences are very similar to cultured picoeukaryotes (Fig. 4(a)). Others clearly affiliate within a given group but are distantly related to its cultured representatives, so likely represent new species or genera (Fig. 4(b)). Other sequences show a profoundly deep distance from all cultured organisms and can only be unambiguously affiliated to a supergroup, such as the marine alveolates (MALV)-I and -II (Fig. 3) and the marine stramenopiles or MAST (Fig. 4(c)). Finally, in a few cases the retrieved sequences form a novel high-rank taxonomic entity that cannot be assigned to any given supergroup, for example, the picozoa.

A summary of the clonal representation in 18S rDNA libraries published until 2008 from surface samples is shown in Table 2. These libraries derive from Atlantic, Pacific, Indian, and Southern oceans and Mediterranean and North seas (35 libraries and 2175 clones). The better-represented phylogenetic groups are alveolates (42.5% of clones), stramenopiles (22.8%), and chlorophytes (15.0%). Some groups are more abundant in coastal libraries (ciliates, MALV-II, cryptophyta, chlorophyta, and cercozoans), whereas others are more abundant in offshore libraries (MASTs, pelagophytes, prymnesiophytes, and radiolarians). Recent work using HTS approaches and using a large collection of samples from the open ocean (Tara Ocean project) or European coastal sites (BioMarKs project) are essentially confirming and expanding the information already gathered by clone libraries. The different levels of phylogenetic novelty shown in Fig. 4 are discussed below.

Relatively Well-Known Groups

Mamiellophytes show the best correspondence between molecular and culturing approaches. They are well represented in both approaches, and environmental sequences are often identical to that of cultured cells, particularly from *M. pusilla*, *O. tauri*, and *B. prasinos*. Using FISH probing, *M. pusilla* has been found to be very abundant in coastal systems (up to 10^5 cells mL^{-1}), supporting previous views from culturing, electron microscopy, and pigment analysis. It appears that a substantial fraction of picoeukaryotes in

Fig. 4 Pelagophytes (a), choanoflagellates (b), and MAST-4 (c) phylogenetic trees with 18S rDNA sequences from the marine picoplankton and closest cultured representatives. Environmental sequences are colored depending on their origin: Atlantic (red), Pacific (green), Indian (gray), Arctic (blue), and Mediterranean (yellow).

Table 2 Clonal representation of phylogenetic groups in 18S rDNA libraries prepared from surface picoplankton from coastal (23 libraries and 1349 clones from Mediterranean, North Sea, English Channel, and Pacific Coast) and offshore (12 libraries and 826 clones from the Mediterranean Sea, Antarctica, and Indian, Pacific, and Atlantic oceans) systems

<i>Chromalveolates</i>		% Total	% Coast	% Offshore	Tendency
Alveolates	Ciliates	4.9	7.6	2.7	Coastal
	Dinoflagellates	5.3	6.1	4.7	
	MALV-I	14.6	13.8	15.2	Coastal

coastal systems are Mamiellophytes (50–90%), and these account for a lower percentage of cells (<20%) in offshore samples. Other picophytoplankton groups with cultured species are poorly represented in clone libraries: only 1% of the clones affiliate with pelagophytes, 0.5% with bolidophytes, and the pinguiophytes are seldom detected. Many pelagophyte sequences are nearly identical to *P. calceolata* (Fig. 4(a)). This species appears to be a widely distributed and significantly abundant marine picoplankton in open ocean systems, as supported by recent FISH probing and HPLC pigment analyses.

Prymnesiophytes are important marine algae and seem to contribute significantly to the picoplankton according to HPLC analysis. Also, many cultured prymnesiophytes have the smallest cell dimension $\leq 3 \mu\text{m}$. Nevertheless, their contribution to clone libraries is moderate (4.5%), and the environmental sequences often form novel clades. FISH probing shows that prymnesiophytes are rather abundant in coastal and offshore samples (more than their clonal abundance would suggest), reaching up to 30% of the picoeukaryote assemblage. Other algal groups detected in clone libraries are the dinoflagellates (5.3%), important marine protists with phototrophic and heterotrophic species. Since the smallest dinoflagellates observed are around $5 \mu\text{m}$, their molecular signal has been interpreted as filtration artifacts, although the presence of picodinoflagellates cannot be excluded. Similar concerns apply to cryptophytes (2.4% of clones) and diatoms (2.5% of clones), although the latter have very small centric and slim pennate species that would pass the $3 \mu\text{m}$ prefilter. A few sequences are close to the dictyochophyte *Florenciella parvula* and others affiliate distantly to the chlorarachniophytes.

Libraries show a large diversity of putatively heterotrophic protists at low clonal abundance. Some of these groups contain cultured heterotrophic pico- and nanoflagellates: apusomonads, bicosoecids, cercozoans, chrysomonads, choanoflagellates, katablepharids, and *Telonema*. Other groups are known to contain osmotrophic or parasitic forms, such as apicomplexa, fungi, labyrinthulids, oomycetes, and pirsonids. A significant number of sequences relate to ciliates (4.9%), important components of the nano- and microzooplankton but at least $10 \mu\text{m}$ in size, so their presence is most likely a filtration artifact. The chrysomonads also show a moderate clonal representation (2.7%) and contain sequences close to well-known heterotrophic flagellates, such as *Paraphysomonas*, as well as novel clades. The trophic mode of these novel chrysomonads is uncertain, but data obtained in plastid rDNA libraries suggest an unexpected importance of chrysomonads within the picophytoeukaryotes. Finally, a substantial fraction of clones affiliate with the radiolarians. This is surprising, since the radiolarian species known so far are rather large (typically between 30 and $300 \mu\text{m}$) and most possess mineralized skeletons. They are virtually absent from coastal systems, and reach a significant clonal abundance in the surface of the open sea (9.8%). Moreover, the fraction of radiolarian sequences increases with depth in the water column, and can reach 20–30% of clones at the bottom of the photic zone and below. Marine radiolarian sequences are diverse and form at least five clades, two related to acanthareans, one to polycystinea, and two to taxopodida. Even though radiolarians can produce small swimmers during their life cycle, it is doubtful that the strong signal encountered derives exclusively from these swimmers, so the presence of radiolarian sequences within the picoplankton is still an unresolved enigma.

Marine Alveolates and Marine Stramenopiles

Environmental surveys have revealed novel clades that affiliate to a given eukaryotic supergroup but without a clear affiliation to any of its members. Among these, the MALV and MAST are particularly interesting because they appear in virtually all marine

surveys at high clonal abundance. MALV are divided into five main groups and two of them MALV-I (five clades) and MALV-II (16 clades) have a very high clonal abundance (14.4 and 17.6%, respectively). The first described MALV-II species was *Amoebophrya*, a dinoflagellate parasite, and additional parasite species have been recently published within both groups. So, it now appears that the whole assemblage might consist of parasites of marine organisms. The specific interaction with different hosts could explain their high level of genetic diversity. This opens new avenues for exploration of the role of parasitism as a trophic mechanism in the open sea. In coastal systems, MALV infection has been seen to control the blooms of dinoflagellate species.

MASTs form up to 18 independent clades at the basal part of the stramenopile tree, where all protists are heterotrophic, free-living flagellates, parasites, osmotrophs, or commensals. This suggests these MASTs are heterotrophs, which has been confirmed by FISH for several clades. On average, MAST sequences account for 13.4% of picoeukaryotic clones, and most of this signal is explained by clades MAST-1, -3, -4, and -7. These are colorless protists, with a size from 2 to 8 μm , able to grow in the dark and to ingest bacteria (Fig. 5). MASTs are widely distributed and account for a significant fraction of heterotrophic flagellates. For example, the very small MAST-4 protist (2–3 μm) is found in all samples except the polar ones, averages 130 cells mL^{-1} , and accounts for 9% of heterotrophic flagellates. This shows that still-uncultured groups can be dominant in marine picoeukaryote assemblages and that model cultured organisms might have limited use for understanding how marine ecosystems work.

Novel High-Rank Phylogenetic Groups

Early molecular surveys claimed the discovery of major novel groups at the highest taxonomic rank, in an effort to highlight the potential of this approach. However, it was soon recognized that some of these novel groups were artifacts due to the presence of undetected chimeras, misplacement of fast-evolving lineages, and incomplete representation of cultured strains. Nevertheless, it is clear that some novel high-rank groups are real and form robust and deep phylogenetic clades that cannot be assigned to any known eukaryotic supergroup. These are generally found at low clonal abundance, so probably are not very important ecologically. Instead, their interest resides in their evolutionary novelty. Perhaps the best example is the picozoa, a novel class that can be locally abundant, and for which a representative isolate was obtained in 2013. Another example would be the Rappemonads, described in 2011 in base of 16S rDNA plastid sequences and whose equivalence to the 18S is still unknown. Indeed, there may be many novel high-rank groups awaiting formal characterization.

Fig. 5 Epifluorescence images of MAST-1B, MAST-1C, and MAST-4 cells. (a) Same microscopic field observed by UV (upper panels: DAPI-stained blue cells) and green light (lower panels: fluorescent in situ hybridization (FISH)-stained orange cells). MAST cells in the upper panels are indicated with a white arrow. (b) Combination of three images in several MAST cells: DAPI staining (blue nucleus), FISH (orange cytoplasm), and ingested FLBs (yellow spots). Scale bar=5 μm .

Biogeography

There is considerable debate about the extent of diversity and biogeographical distribution of microorganisms. It has been argued that given the huge population sizes and the potential for distant dispersal, most microbial species must be cosmopolitan and the total number of species must be relatively low. This is what is observed using the morphospecies concept to identify protists. However, this concept cannot account for cryptic species, the level of which may not be insignificant among protists, given that the same morphospecies can belong to genetically, reproductively, and ecologically isolated groups. Thus, the use of molecular tools to compare assemblages from distant systems provides more systematic and objective assessment of the extent of protist biogeography and diversity.

Clone libraries from widely separated picoeukaryote assemblages yield similar phylogenetic groups, suggesting that their overall community structure is comparable on a worldwide scale. Further, there appears to be no particular geographic separation as identical 18S rDNA sequences have been retrieved from distant oceans (Fig. 4). Altogether, we find little sign of geographic barriers for picoeukaryotes in the marine environment, and most groups seem to be roughly globally distributed. This supports the cosmopolitan view mentioned above, although finer resolution markers than 18S rDNA might be needed to detect locally adapted populations.

Global distribution has been used as an argument for low protist diversity as it should prevent speciation by geographic isolation or allopatry, the speciation mechanism considered most important. However, most taxonomic groups detected in environmental surveys show a large 18S rDNA sequence variability, thus disagreeing with the view of low protist diversity. The significance of this large intragroup rDNA diversity is presently not understood but can be relevant, since differences as small as 1% in the 18S rDNA might imply millions of years of evolutionary distance. It is also not clear how this large phylogenetic diversity of protists translates into functional diversity in the open sea or how this diversity is generated and maintained. One possibility is to view the seemingly homogeneous pelagic habitat as a continuum of environmental niches. Thus, there is a large genetic diversity of marine protists, which may have a global distribution, but the ecological implications of this large diversity remain to be investigated.

The Genomic Era

Genome Projects on Species of Picoeukaryotes

There has been an increasing effort in recent years to expand databases of genome sequences of microbial species in order to recover a good representation of the eukaryotic tree of life. Seminal projects used cultured species, which were needed to recover enough DNA for genome sequencing, and were often accompanied by parallel transcriptomic projects, i.e., the sequencing of total mRNA. Many of these genomes were derived from species with socio-economic importance like pathogens or parasites, but a number of free-living protists were also analyzed, such as the diatoms *Thalassiosira pseudonana* and *Phaeodactylum tricornutum*, the mamiellophytes *Ostreococcus*, *Micromonas*, and *Bathycoccus*, the green algae *Chlamydomonas reinhardtii*, the ciliates *Paramecium tetraurelia* and *Tetrahymena thermophila* and the choanoflagellate *Monosiga brevicollis*. Each genome was analyzed from a different evolutionary perspective, for example, searching for gene organization, speciation patterns, or the origin of multicellularity. Genomes can also reveal the gene basis of the ecological success. It is recognized that genomic data is pivotal for understanding the cellular function and evolutionary diversity of all living organisms.

The first picoeukaryote to be genome sequenced was *O. tauri*. This minute species has a 12.56 Mb haploid nuclear genome organized in 20 chromosomes. This genome is highly compacted, mainly due to the reduction in size of intergenic regions and the low copy numbers of most genes. The 8166 identified genes include all basic cell functions, such as photosynthesis, central metabolism, and cell–environment interaction. Genes encoding enzymes for C4-photosynthesis have been identified, which may help the cells adapt to the limiting CO₂ concentrations of phytoplankton blooms. There are genes for transport and assimilation of nitrate, ammonium, and urea, and the larger number of ammonium transporters as compared to nitrate transporters indicates that *O. tauri* could be a strong competitor for ammonium, which is uncommon in eukaryotic algae. *O. tauri* also has two chromosomes that differ structurally, being biased toward a lower GC content and a larger number of transposable elements. The first seems to have an alien origin, while the second could represent a sexual chromosome, preventing recombination with similar but not identical strains. Genes related to meiosis have been identified and are apparently functional, suggesting that this protist that usually reproduces asexually may also possess a sexual phase not yet observed but inferred from recombination signatures detected in hypervariable regions of the genomes. Thus, the genome of *O. tauri* follows prediction of compaction that might be driven by its specific lifestyle and ecology.

Genomic projects are no longer limited by the availability of relevant ecological models for culturing. Single cell genomics (SCG) is an emerging technology in biological sciences that has recently become feasible due to the improvements in single cell manipulation, whole genome amplification, high-throughput sequencing and bioinformatics. For the first time, these tools enable the sequencing of genomes of individual cells. SCG exploration of the plethora of ecologically dominant but elusive microbial eukaryotes offer tremendous promises to advance in multiple research fields, including ecology, evolution, and biotechnology. Applying SCG to microbial eukaryotes is still in its infancy, and is particularly challenging when compared to SCG on prokaryotes, because of target genomes of greater complexity (multiple chromosomes, introns, low codon density, high numbers of repeats, large gene paralogue families). Despite these difficulties, analyzing genomes of single picoeukaryote cells will be crucial to obtain the *de novo* genomes of uncultured lineages and to study the genome variability within natural populations.

Environmental Genomics or Metagenomics

A striking advance in microbial ecology has been the gathering of gene content of natural communities, an approach that is not culture-dependent nor hypothesis-driven. There were initially two main strategies depending on the size of the DNA being cloned. Large DNA fragments (40–200 kb) were cloned in bacterial artificial chromosomes (BAC) or fosmid vectors, and clones with these large inserts were screened before being completely sequenced. This provided complete operon information, and in the case of prokaryotes also linked phylogenetic and functional markers. Alternatively, small DNA fragments (3–5 kb) were cloned by routine methods and randomly sequenced at high throughput, which was known as shotgun sequencing. This provided a large amount of genetic data, but the short sequences obtained were difficult to assemble due to the large diversity of natural assemblages. Today, metagenomic studies are clearly benefiting from the application of HTS, which resulted in a much larger number of shorter sequences, but which also generates corresponding bioinformatic challenges. Metagenomic approaches have been particularly useful for marine bacteria and archaea, to identify previously unknown metabolic pathways, such as novel uses of light and reduced compounds to generate energy, and putatively novel enzymes, antibiotics, and signaling molecules. This approach has not yet been routinely applied to picoeukaryotes, which are prefiltered from most of the analyzed samples. The combination of single gene sequencing (typically the 18S rDNA), isolation in pure culture, single cell genomics and metagenomics offer new opportunities for a complete understanding of picoeukaryote performance in marine ecosystems.

Concluding Remarks

Picoeukaryotes are very small organisms ($\leq 3 \mu\text{m}$ in the maximal dimension) that are morphologically and structurally simple but with all components required for an independent life. It is fascinating to find all organelles necessary for cell metabolism, growth, and reproduction assembled in such a small package. The few model cultures available so far provide useful tools for ecophysiological and genomic studies. In the marine environment, picoeukaryotes are ubiquitous, account for a significant share of planktonic biomass, and play key ecological roles as primary producers, bacterial predators, and parasites of marine life. The true diversity contained in marine picoeukaryotes has been recently unveiled by the use of molecular tools, which have revealed a very high diversity within this assemblage and the presence of many novel eukaryotes uncharacterized and uncultured. This increase in diversity occurs at almost all possible phylogenetic scales: high-rank novel groups, novel clades within supergroups, and putatively new species, genera, families, and orders within known lineages. The challenge is to retrieve in culture these novel organisms and to determine their trophic role and ecological function. The implication of this large and novel eukaryotic diversity for biodiversity surveys and ecosystem functioning opens new avenues for future research.

Glossary

Astaxanthin A reddish carotenoid pigment found in salmon, crustacean shells, and bird feathers (e.g., pink flamingos).

Bacteriochlorophyll A form of chlorophyll present in photosynthetic bacteria.

Carotenoids A group of yellow, orange, or red polyene pigments produced in plants and certain microorganisms. Divided into carotenes (hydrocarbons) and xanthophylls (oxygenated carotenes).

Color The sensation resulting from stimulation of the retina of the eye by light waves of certain lengths.

Melanins High molecular weight polymeric indole quinine pigments having brown or black colors.

Phenazines Compounds based on the tricyclic phenazine ring system, some of which are colored, and are secreted by some species of bacteria.

Pigment Any coloring matter in microbial, plant, or animal cells.

Defining Statement

Microorganisms have been used for a long time for production of molecules as diverse as antibiotics, enzymes, vitamins, texturizing agents, and so on. In nature, pigmented bacteria, yeasts, or fungi are quite common, and the main functions of pigments in these living organisms are related to light. The industry is now able to produce some microbial pigments for applications in food, cosmetics, or textile.

Introduction

Nature is rich in colors (minerals, plants, microalgae, etc.), and pigment-producing microorganisms (fungi, yeasts, and bacteria) are quite common (Fig. 1). Among the molecules produced by microorganisms are carotenoids, melanins (Plonka and Grabacka, 2006), flavins, phenazines (Kerr, 2000), quinones, bacteriochlorophylls, and more specifically monascins, violacein, or indigo (Fig. 2; Dufossé, 2004). The success of any pigment produced by fermentation depends on its acceptability in the market, regulatory approval, and the size of the capital investment required to bring the product to market. A few years ago, some expressed doubts about the successful commercialization of fermentation-derived food grade or cosmetic grade pigments because of the high capital investment requirements for fermentation facilities and the extensive and lengthy toxicity studies required by regulatory agencies.

[☆]Change History: June 2016. Laurent Dufossé updated text and references throughout the article.

This article is an update of L. Dufossé, Pigments, Microbial, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 457–471.

Fig. 1 Spontaneous development of pigmented microorganisms at the surface of nutritive agar Petri dish.

Public perception of biotechnology-derived products also had to be taken into account. Nowadays some fermentative food grade pigments are on the market: *Monascus* pigments, astaxanthin from *Xanthophyllomyces dendrorhous* or *Paracoccus carotinifaciens*, Arpink Red (or Natural Red) from *Penicillium oxalicum*, riboflavin from *Ashbya gossypii*, and β -carotene or lycopene from *Blakeslea trispora*. The successful marketing of pigments derived from algae or extracted from plants, both as a food color and a nutritional supplement, reflects the presence and importance of niche markets in which consumers are willing to pay a premium for “all natural ingredients.”

Color plays a special role in the food we eat. For example, when confronted with an unattractive color, the consumer assumes that the food is poor or spoiled. On the other hand, products with atypical color – for example, green cheese or blue drink – in most cases, are rejected by the consumers. Typically, one associates colors with food items, such as cherry with red, lemon with yellow, or carrot with orange. Therefore, colors can serve as the primary identification of food and are also a protective measure against the consumption of spoiled food. Colors of foods create physiological and psychological expectations and attitudes that are developed by experience, tradition, education, and environment: “We inevitably eat with our eyes.”

The controversial topic of “synthetic dyes in food” has been discussed for many years (Mapari et al., 2005). The scrutiny and negative assessment of synthetic food dyes by the modern consumer have given rise to a strong interest in natural coloring alternatives. Some companies decided to “color food with food,” using mainly plant extracts or pigments from plants, for example, red from paprika, beetroots, berries, or tomato; yellow from saffron or marigold; orange from annatto; green from leafy vegetables.

Penetration of the fermentation-derived ingredients into the food and cosmetic industries is increasing year after year. Examples could be taken from the following fields: thickening or gelling agents (xanthan, curdlan, and gellan), flavor enhancers (yeast hydrolysate and monosodium glutamate), flavor compounds (gamma-decalactone and diacetyl, methyl-ketones), and acidulants (lactic acid and citric acid). Efforts have been made in order to reduce the production costs of fermentation pigments compared to those of synthetic pigments or pigments extracted from natural sources. Innovations will improve the economy of pigment production by isolating new or creating better microorganisms, by improving the processes. This article focuses on research works related to this field published over the past 10 years by private companies or academic laboratories, with an emphasis on pigments for food use. As recently described by our group, there is “a long way from the Petri dish to the market place,” and thus to the product on store shelves.

Monascus Pigments – An Old Story for Asians

Monascus Pigment

Monascus is cultivated on solid medium in Asian countries to produce a red colorant named “Anka” used as a food ingredient. In a Chinese medical book on herbs published in the 1st century, this term “ang-kak” or “red mold rice” was first mentioned. Red mold rice has been used as a food colorant or spice in cooking. In 1884, a purple mold was isolated on potato and linseed cakes and was named *Monascus ruber*. This ascomycete was so named as it has only one polyspored ascus. Then in 1895 another strain was isolated from the red mold rice obtained from the market in Java, Indonesia. This fungus was named *Monascus purpureus*. Later, several other species were isolated around the world. *Monascus* is often encountered in oriental foods, especially in southern China, Japan, and Southeastern Asia. Currently, more than 50 patents have been issued in Japan, the United States, France, and Germany, concerning the use of *Monascus* pigments for food. Annual consumption of *Monascus* pigments in Japan moved from 100 t in 1981 to 600 t at the end of the 1990s and was valued at \$1.5 million. New food applications, like the coloration of processed meats (sausage and hams) and marine products like fish paste, surimi, and tomato ketchup, were described.

Fig. 2 Chemical formulae of some microbial food-grade pigments.

The Fungus *Monascus*

The genus *Monascus* was divided into three species: *pilosus*, *purpureus*, and *ruber*, which comprise the majority of the strains mainly isolated in oriental food.

The Fungal Metabolites

The main metabolites produced by *Monascus* are polyketides, which are formed by the condensation of one acetylCoA with one or more malonylCoA with a simultaneous decarboxylation as in the case of lipidic synthesis. They consist of the pigments, monacolins, and, under certain conditions, a mycotoxin.

Monascus pigments are a group of fungal polyketide metabolites called azaphilones, which have similar molecular structures as well as similar chemical properties. Two molecular structures of the *Monascus* pigments are shown on Fig. 2. Ankaflavine and monascin are yellow pigments, rubropunctatine and monascorubrine are orange, and rubropunctamine and monascorubramine are purple. The same color exists in two molecular structures differing in the length of the aliphatic chain. These pigments are produced mainly in the cell-bound state.

They have low water solubility, are sensitive to heat, unstable in the pH range of 2–10, and fade with light. A number of methods have been patented in order to make water-soluble pigments. The principle is the substitution of the replaceable oxygen in monascorubrine or rubropunctatine by nitrogen of the amino group of various compounds such as amino acids, peptides, and proteins, changing the color from orange to purple. *Monascus* pigments can be reduced, oxidized, and react with other products, especially amino acids, to form various derivative products sometimes called the complexed pigments. Glutamyl-monascorubrine and glutamyl-rubropunctatine were isolated from the broth of a submerged culture.

Stability of the pigments is affected by acidity, temperature, light, oxygen, water activity, and time. It was shown that these pigments added to sausages or canned pâté remained stable for 3 months' storage at 4°C, while their stability ranged from 92 to 98%. Thus, the main patents have focused on the solubilization, the stability and the extraction in solution of pigments. The pigments can easily react with amino group-containing compounds in the medium, such as proteins, amino acids, and nucleic acids, to form water-soluble pigments.

A series of hypocholesteremic agents has been isolated from *Monascus* and named monacolin J, K, and L. These polyketides were first isolated from cultures of *Penicillium citrinum* and they can inhibit specifically the enzyme controlling the rate of cholesterol biosynthesis. They are currently used in China in traditional and modern medicine.

Antibacterial properties of *Monascus* were first mentioned in 1977. The so-called monascidin A was effective against *Bacillus*, *Streptococcus*, and *Pseudomonas*. It was shown that this molecule was citrinin and its production by various *Monascus* species was studied using different culture media and conditions.

The Production in Various Modes of Cultures

Submerged cultures

Considerable contradiction exists in the published works as to the best carbon source for red pigment production in liquid cultures. Traditionally cultured on breads and rice, *Monascus* grows on every amylaceous substrate. *Monascus* grows quite well on starch, dextrans, glucose, maltose, and fructose. High production of pigments was achieved using glucose and maltose. The nitrogen source seems to have more importance than the carbon source and ammonium, and peptones as nitrogen sources gave superior growth and pigment concentrations compared to nitrate. The best results were obtained using glucose and histidine. The C/N ratio was also shown to be important: at a value close to 50 g g⁻¹ growth would then be favored, while in the region of 7–9 g g⁻¹, pigmentation would be favored.

Solid-state cultures

The classical Chinese method consists in inoculating steamed rice grains spread on big trays with a strain of *Monascus anka* and incubating in an aerated and temperature-controlled room for 20 days.

In these types of cultures, moisture content, oxygen and carbon dioxide levels in the gas environment, as well as cereal medium composition, are the most important parameters to control.

Moisture content is a very important parameter. Red pigments were produced in plastic bags containing rice grains. It was observed that pigmentation occurred only at a relatively low initial moisture level (26–32%). Initial substrate moisture content regulated pigmentation as it was found that glucoamylase activity increased along with a rise in initial substrate moisture content. Therefore, at high moisture content, as high enzyme activity was produced, glucose was rapidly liberated in amounts (120 g L⁻¹), which inhibited pigmentation. The sugar was then transformed into ethanol.

As far as cultures on rice are concerned, an optimal pigmentation was found at an initial moisture content of 56%, while lower moisture contents led to a large decrease in pigment formation. Thus, it was confirmed that solid culture was superior to liquid culture for red pigment production by *M. purpureus*. This result has been attributed to the derepression of pigment synthesis in solid systems due to the diffusion of intracellular pigments into the surrounding solid matrix. In submerged culture, the pigments normally remain in the mycelium due to their low solubility in the usually acidic medium.

Levels of oxygen and carbon dioxide in the gas environment influence pigment production significantly while affecting growth to a lesser extent in solid state culture. With *M. purpureus* on rice, maximum pigment yields were observed at 0.5×105 Pa of oxygen partial pressure in closed pressure vessels. However, high carbon dioxide partial pressures progressively inhibited pigment production, with complete inhibition at 105 Pa. In a closed aeration system with a packed-bed fermentor, oxygen partial pressures ranging from 0.05 to 0.5×105 Pa at constant carbon dioxide partial pressures of 0.02×105 Pa gave high pigment yields with a maximum at 0.5×105 Pa of oxygen, whereas lower carbon dioxide partial pressures at constant oxygen partial pressures of 0.21×105 Pa gave higher pigment yields. Maximum oxygen uptake and carbon dioxide production rates were observed at 70–90 and 60–80 h respectively, depending on the gas environment. Respiratory quotients were close to 1.0 except at 0.05×105 Pa of oxygen and 0.02×105 Pa of carbon dioxide partial pressures.

When studying various cereal media, it was shown that the best results were obtained using “mantou” meal (yeast-fermented wheat meal).

Methods Developed to Avoid Mycotoxin Production

In order to identify chemically the so-called monascidin A discussed by some Chinese scientists in their papers as a component suitable for the preservation of food, it was isolated and chemical investigations using mass spectrometry and NMR were undertaken. Monascidin A was characterized as citrinin. Thus, in order to avoid the production of this toxin, various strains were screened in order to see if all were toxinogenic, and it was shown that in the species of *Monascus* available in public collections, nontoxinogenic strains were obtainable.

Another way to avoid the production of citrinin can be through controlling the biosynthesis of the metabolite. To control the biosynthesis, the metabolic pathway has to be investigated. The metabolic pathway is the same for citrinin and the pigment: the polyketide pathway in which condensation of acetates and malonates occurred. In the case of the pigment, there is at the end of the pathway an esterification of a fatty acid on the chromophore to obtain the colored molecules. Several modifications of the culture conditions are possible in order to increase the pigment production or reduce the citrinin one: addition of fatty acids and change of the nitrogen source. Adding fatty acids to the medium was effective in favoring the synthesis of pigment, but the citrinin production remained unchanged.

The final modification of the culture conditions was the replacement of glutamic acid by other amino acids. *M. ruber* was cultivated in a liquid medium containing glucose and various amino acids, and histidine was found to be the most effective nitrogen source regarding citrinin production inhibition. When the pathway of histidine assimilation was investigated, it was shown that during its catabolism, one molecule of hydrogen peroxide was produced per molecule of consumed histidine, and it is known that peroxidases can destroy citrinin in the presence of hydrogen peroxide. So, the production of citrinin can be avoided by control of the medium especially by the selection of a suitable amino acid, usually histidine.

Despite the enormous economic potential of *Monascus* pigment, it does not lead to a commercial exploitation in the Western world, mainly because of ignorance and also reluctance to change from food public agencies. Indeed these agencies do not approve *Monascus* pigments for use in the food industry, although they do appear to be non-toxic if correctly used. Thus, even though species of *Monascus* have been consumed in the Far East for many years, this does not help the pigment to gain approval in the European Union or the United States.

Using next-generation sequencing and optical mapping approaches, a 24.1-Mb complete genome of a *M. purpureus* YY-1 industrial strain has been described for the first time and this will allow huge improvements in the process in the coming years (Yang et al., 2015). It consists of eight chromosomes and 7491 genes. *M. purpureus* should belong to the Aspergillaceae, mainly comprising the genera *Monascus*, *Penicillium*, and *Aspergillus*. Phylogenetic analysis at the genome level provides the first comprehensive prediction of the biosynthetic pathway for *Monascus* pigments. Comparative genomic analyses demonstrated that the genome of *M. purpureus* is 13.6–40% smaller than that of closely related filamentous fungi and has undergone significant gene losses, most of which likely occurred during its specialized adaptation to starch-based foods. Some polyketide synthases (PKS) are expressed at high levels under high pigment yielding conditions. The citrinin PKS C6.123 has also been found in the genome, paving the way for research aiming at non-mycotoxin producing strains, if suppression of the citrinin gene does not change the ability of the strain to produce pigments, which seems to be feasible, as it seems that monascorubin and citrinin are synthesized by two separate pathways, because, when the PKS gene responsible for synthesis of citrinin was disrupted, red pigment production from the fungus was not affected. Comparative transcriptome analysis revealed that carbon starvation stress, resulting from the use of relatively low-quality carbon sources, contributed to the high yield of pigments by suppressing central carbon metabolism and augmenting the acetyl-CoA pool. As for other pigments produced by biotechnology, the problem is to have enough carbon oriented in the correct pathway, i.e., the pigment pathway.

Monascus-Like Pigments From Non-Toxigenic Fungal Strains

Some species of *Talaromyces* secrete large amounts of red pigments. In the literature, this biosynthetic potential has been linked to species such as *Talaromyces purpurogenus*, *Talaromyces marneffeii*, and *Talaromyces minioluteus* often known under their previous *Penicillium* names. However, since some of them do not exert enough stability for pigment production, then such species should be avoided for scale-up production.

Isolates identified as *T. purpurogenus* have been reported to be of industrial interest. They can produce extracellular enzymes and red pigments, but may also produce mycotoxins such as rubratoxin A and B and luteoskyrin in addition to extrolites that may be toxic following intraperitoneal (spiculisporic acid) and intravenous (rugulovasine A and B) injections in cats. Consequently, mycotoxin production may limit the use of isolates of a particular species in biotechnology, and some authors concluded that *T. purpurogenus* may thus not be recommended for industrial production of red pigments. *Talaromyces atrovirens* sp. nov. produces the azaphilone biosynthetic families mitorubins (Frisvad et al., 2013) and *Monascus* like-pigments without being accompanied by mycotoxin synthesis (patent applications WO2012022765, US 20110250656). As it has been found for *Monascus*, these azaphilone pigments may react with amino groups containing compounds, to which reaction they owe their name, providing intense dark red colors. *Talaromyces albobiverticillius* isolated from Réunion island lagoon, Indian Ocean, is also under investigation.

Arpink Red From *Penicillium oxalicum* – Still a Strange and Unclear Case

Many patents from Ascolor s.r.o. (Czech Republic) relate to a new fungus strain having the properties to produce a red colorant that can be applied in the food and cosmetic industries (WO9950434, CZ285721, EP1070136, US6340586). The strain *P. oxalicum* var. *Armeniaca* CCM 8242, obtained from soil, produces a chromophore of the anthraquinone type (Figs. 1 and 3). Some strains of the same species are effective as biological control agents, for example, reduction of the incidence of *Fusarium* wilt of tomato under glasshouse and field conditions. Others have been described for production of a milk-clotting enzyme.

Fig. 3 Some anthraquinones from fungal origin (A) maroon, (B) bronze, (C) yellow, (D) red-orange (color of the box reflects color of the main pigment produced by the fungus).

The cultivation of the fungus in liquid broth requires carbohydrates (such as sucrose and molasses), nitrogen (corn extract and yeast autolysate or extract), zinc sulfate, and magnesium sulfate. The optimum conditions for performing the microbiological synthesis are pH value 5.6–6.2 and temperature 27–29°C.

On the second day of incubation a red colorant is released into the broth, increasing up to 1.5–2.0 g L⁻¹ of broth after 3–4 days. After biosynthesis of the red colorant is completed, the liquid from the broth is filtered or centrifuged for being separated from the biomass. The liquid is then acidified to pH 3.0–2.5 to precipitate the colorant. The precipitate is dissolved in ethyl alcohol and filtered. Following removal of alcohol, the colorant in the crystalline form is obtained, that is, dark red powder.

The colorant gives a raspberry red color in aqueous solution, stable at pH over 3.5. Neutral solutions are stable even after 30 min of boiling and color shade does not change in relation with pH.

Many toxicological data are available on this red pigment: acute oral toxicity in mice 90-day subchronical toxicological study, acute dermal irritation/corrosion, acute eye irritation/corrosion, antitumor effectiveness, micronucleus test in mice, AMES test (*Salmonella typhimurium* reverse mutation assay), estimation of antibiotic activity, and results of estimation of five mycotoxins. A new patent on Arpink Red was filed in 2001 with claims of anticancer effects of the anthraquinone derivatives and applications within the food and pharmaceutical fields.

After evaluating all the materials provided by the company Ascolor s.r.o., the Codex Alimentarius Commission (Rotterdam meeting, 11–15 March 2002) made the following statement: “there will not be any objections to use the red coloring matter Arpink Red” in:

- meat products in the amount up to 100 mg kg⁻¹,
- meat and meat product analogs in the amount up to 100 mg kg⁻¹,
- nonalcoholic drinks in the amount up to 100 mg kg⁻¹,
- alcoholic drinks in the amount up to 200 mg kg⁻¹,
- milk products in the amount up to 150 mg kg⁻¹,
- ice creams in the amount up to 150 mg kg⁻¹,
- confectionery in the amount up to 300 mg kg⁻¹.

JECFA evaluation process is in progress and Arpink Red situation was discussed during the 63rd meeting of Joint FAO/WHO Expert Committee on Food Additives in Geneva, 8–17 June 2004. File is also under progress at the European Food Safety Authority (EFSA) under the reference EFSA-Q-2007-021.

Other Fungal Anthraquinones

Anthraquinones are widely spread in the kingdom of fungi (Fouillaud et al., 2016), and thus, the latter might serve as alternative sources being independent of agro-climatic conditions in contrast to plant and animal derived sources. For example, anthraquinones were found in *Aspergillus* sp., *Eurotium* sp., *Fusarium* sp., *Dreschlera* sp., *Penicillium* sp., *Emericella purpurea*, *Curvularia lunata*, *Mycosphaerella rubella*, *Microsporum* sp., etc.

Anthraquinones exhibit a broad range of biological activities, including bacteriostatic, fungicidal, antiviral, herbicidal, and insecticidal effects. Presumably, in fungi, these compounds are involved in interspecific interactions. For example, anthraquinones synthesized by endophytic fungi protect the host plant from insects or other microorganisms.

The present picture of fungal anthraquinones is quite complex, with a great variety of chemical structures, a huge number of factors or parameters which may have impact on the composition of quinoidal pigments biosynthesized by a particular species. Among them, for example, habitat, light, pH, temperature, O₂ transfer, liquid/solid media, culture medium, C and N sources, C:N ratio, presence of organic acids, mineral salts, and inoculum have been considered.

Today, research priority is laid on a small number of fungal anthraquinone-producing species meeting the following profile of requirements established during the identification of potentially safe fungal cell factories for the production of polyketide natural food colorants using chemotaxonomic rationale:

- fungus shall be non-pathogenic to humans,
- fungus shall be non-toxicogenic under a broad range of production conditions,
- fungus shall be able to produce in liquid media.

Riboflavin – The Vitamin B2 But Also a Yellow Food Colorant

Riboflavin (vitamin B2) has a variety of applications as a yellow food colorant. Its use is permitted in most countries. Applications include dressings, sherbet, beverages, instant desserts, ice creams, tablets, and other products. Riboflavin has a special affinity for cereal-based products, but its use in these applications is somewhat limited due to its slight odor and naturally bitter taste. There are numerous microorganisms that produce riboflavin fermentatively. Riboflavin fermentation could be classified into three categories: weak overproducers (100 mg L⁻¹ or less, e.g., *Clostridium acetobutylicum*), moderate overproducers

(up to 600 mg L⁻¹, e.g., yeasts such as *Candida guilliermondii* or *Debaryomyces subglobosus*), and strong overproducers (over 1 g L⁻¹, e.g., the fungi *Eremothecium ashbyii* and *A. gossypii*).

Current Carotenoid Production Using Microorganisms

Commercial processes are already in operation or under development for the production of carotenoids by molds, yeasts, and bacteria. The production of β -carotene by microorganisms, as well as by chemical synthesis or from plant extracts is well developed (Table 1; Britton et al., 2004), and several other carotenoids, notably lycopene, astaxanthin, zeaxanthin, and canthaxanthin are also of interest.

β -Carotene

β -Carotene from *Blakeslea trispora*

The source organism, *B. trispora*, is a commensal mold associated with tropical plants. The fungus exists in (+) and (−) mating types, of which the (+) type synthesizes trisporic acid, a metabolite of β -carotene. On mating the two types in a specific ratio, the (−) is stimulated by trisporic acid to synthesize large amounts of β -carotene. The mold has shown no pathogenicity or toxicity, in standard pathogenicity tests in mice, by analyses of extracts of several fermentation mashers for fungal toxins and by enzyme immunoassays of the final product, the β -carotene crystals, for four mycotoxins.

The production process proceeds essentially in two stages. Glucose and corn steep liquor can be used as carbon and nitrogen sources. Whey, a by-product of cheese manufacture, has also been considered, with strains adapted to metabolize lactose. In the initial fermentation process, seed cultures are produced from the original strain cultures and subsequently used in an aerobic submerged batch fermentation to produce a biomass rich in β -carotene. In the second stage, the recovery process, the biomass is isolated and transformed into a form suitable for isolating the β -carotene, which is extracted with ethyl acetate, suitably purified and concentrated, and the β -carotene crystallized. The final product is either used as crystalline β -carotene (purity 96%) or is formulated as a 30% suspension of micronized crystals in vegetable oil. The production process is subject to Good Manufacturing Practices (GMP) procedures, and adequate control of hygiene and raw materials. The biomass and the final crystalline product comply with an adequate chemical and microbiological specification and the final crystalline product also complies with the JECFA (Joint FAO/WHO Expert Committee on Food Additives) and EU specifications as set out in Directive 95/45/EC for coloring materials in food.

The first β -carotene product from *B. trispora* was launched in 1995 at the Food Ingredients Europe business meeting in London. Following the optimization of the fermentation process, many aspects had to be addressed many aspects before the product could be marketed:

- Presentation of the microorganism: A fungus isolated from a natural environment, not genetically modified; yield improvement achieved by classical genetics.
- Guidelines for labeling: Natural β -carotene; natural β -carotene from *B. trispora*; fermentative, natural β -carotene; natural β -carotene from a fermentative source.
- Lobbying from other β -carotene producers (nature-identical, mixed carotenes from palm oil, β -carotene from the microalgae *Dunaliella*): The EU Health and Consumer Protection Directorate General was asked to give an opinion on the safety of β -carotene from a dried biomass source, obtained from a fermentation process with *B. trispora*, for use as a coloring matter for foodstuffs.
- Safety of the fermentation-produced β -carotene: HPLC analysis, stability tests, and microbiological tests have shown that the β -carotene obtained by cofermentation of *B. trispora* complies with the EC specification for E 160 a(ii), also including the proportions of cis and trans isomers, and is free of mycotoxins or other toxic metabolites. Tests in vitro for gene mutations and chromosomal aberrations with the β -carotene produced by the manufacturer in the European Union showed it to be free of

Table 1 Microorganisms, a carotenoid source among many others. β -Carotene and β -carotene-containing preparations from various sources

Trademark	Company	Origin

genotoxic activity. In a 28-day feeding study in rats with the β -carotene manufactured in the European Union, no adverse findings were noted at a dose of 5% in the diet, the highest dose level used. In conclusion, evaluation of the source organism and the production process yielded no grounds to suppose that the final crystalline product, β -carotene, differs from the chemically synthesized β -carotene used as a food colorant. The final crystalline fermentation product has been shown to comply with the specification for β -carotene E 160 a(ii) listed in Directive 95/45/EC. The committee considers that “ β -carotene produced by co-fermentation of *B. trispora* is equivalent to the chemically synthesized material used as food colorant and is therefore acceptable for use as a coloring agent for foodstuffs” (Table 2).

Today there are other industrial productions of β -carotene from *B. trispora* in Russia and Ukraine, and in León (Spain). The process has been developed to yield up to 30 mg of β -carotene per gram dry mass or about 17 g L^{-1} . *B. trispora* is now also used for the production of lycopene.

β -Carotene from *Phycomyces blakesleeanus*

Another mold, *P. blakesleeanus*, is a potential source for various chemicals including β -carotene. The carotene content of the wild-type grown under standard conditions is modest, about 0.05 mg per gram dry mass, but some mutants accumulate up to 10 mg g^{-1} . As for *B. trispora*, sexual stimulation of carotene biosynthesis is essential and can increase yields up to 35 mg g^{-1} . The most productive strains of *Phycomyces* achieve their full carotenogenic potential on solid substrates or in liquid media without agitation. *B. trispora* is more appropriate for production in usual fermenters.

β -Carotene from *Mucor circinelloides*

M. circinelloides wild type is yellow because it accumulates β -carotene as the main carotenoid. The basic features of carotenoid biosynthesis, including photoinduction, are similar in *Phycomyces* and *Mucor*. *M. circinelloides* responds to blue light by activating biosynthesis. Wild-type strains grown in darkness contain minimal amounts of β -carotene because of the low levels of transcription of the structural genes for carotenogenesis. When exposed to a light pulse, the level of transcription of these genes increases strongly, leading to high pigment concentrations. *M. circinelloides* is a dimorphic fungus that grows either as yeast cells or in a mycelium form, and research is now focused on yeast-like mutants that could be useful in a biotechnological production.

Applications of β -carotene

Research reports indicate that natural β -carotene possesses numerous benefits for the human body and consistently support the use of β -carotene as part of the human diet. The human body converts β -carotene to vitamin A via body tissues as opposed to the liver, hence avoiding a buildup of toxins in the liver. Vitamin A is essential for the human body in that it assists the body's immune system and helps battle eye diseases, such as cataracts and night blindness, various skin ailments such as acne, signs of aging, and various forms of cancer. β -Carotene has antioxidant qualities. Antioxidants help mediate the harmful effects of free radicals, which are implied in over 60 life-threatening diseases including various forms of cancer, coronary heart disease, premature aging, and arthritis. Additionally, the antioxidant qualities of β -carotene assist the body in suppressing the effects of premature aging caused by UV rays. β -Carotene is also added to numerous cosmetic and body-care products as a nonharmful colorant to improve the attractiveness of the product.

β -Carotene is one of the leading food colorants in the world. β -Carotene has been applied to a range of food and beverage products to improve their appearance to customers, including items such as margarine, cheese, fruit juices, baked goods, dairy products, canned goods, confectionary, and health condiments, to name just a few. β -Carotene is used in various pet foods as both a colorant and a precursor to vitamin A. β -Carotene can be applied to an array of animal foods designed for pets, including dogs, cats, fish, and birds. The antioxidant and precursory vitamin A properties increase the appeal and application of β -carotene in pet foods. Additionally, β -carotene is an important carotenoid that may assist in improving the color of birds, fish, and crustaceans, as well as improving the appearance of the pet food.

Lycopene

Lycopene is an intermediate in the biosynthesis of all dicyclic carotenoids, including β -carotene. In principle, therefore, blocking the cyclization reaction and the cyclase enzyme by mutation or inhibition will lead to the accumulation of lycopene. This strategy is employed for the commercial production of lycopene.

Lycopene from *Blakeslea trispora*

A process for lycopene production by *B. trispora* is now established, with the aim of marketing this product in Europe for use as a nutritional food ingredient and dietary supplement or a food color. Lycopene is an intermediate in the β -carotene biosynthetic pathway and microbial strains that accumulate lycopene are easy to obtain by mutagenesis, molecular biology, or use of inhibitors. In the commercial process imidazole or pyridine is added to the culture broth to inhibit the enzyme lycopene cyclase. The product, predominantly (all-trans)-lycopene (Table 3), is formulated into a 20 or 5% suspension in sunflower oil with α -tocopherol at 1% of the lycopene level. Also available is an α -tocopherol-containing 10 and 20% lycopene cold water dispersible (CWD) product. Lycopene oil suspension is intended for use as a food ingredient and in dietary supplements. The proposed level of use for lycopene in food supplements is 20 mg day⁻¹.

Approval for the use of lycopene from *B. trispora* was sought under regulation (EC) No 258/97 of the European Parliament and the Council concerning novel foods and novel food ingredients. The European Food Safety Authority was also asked to evaluate this product for use as a food color. It was stated in the application that it is likely that lycopene from *B. trispora* in food supplements would simply replace those supplements containing lycopene from other sources that are already being marketed so that overall consumption levels would not increase. Incorporation of lycopene into foods would result in additional intake.

The dossier first satisfied the United Kingdom Advisory Committee on Novel Foods and Processes (ACNFP) in 2004, but the panel from the European Food Safety Authority, in opinions adopted on 21 April and 5 October 2005, was unable to conclude whether the proposed use levels of lycopene from *B. trispora* would be safe.

Existing authorizations and evaluations on lycopene from various sources are quite numerous. Lycopene, extracted from tomatoes, is authorized as food coloring agent within the European Union (E160d) (Directive 94/36/EC) and the United States (CDR 21 73.295). This restricts the amount that can be added to foods. Lycopene was evaluated by the Scientific Committee on Food (SCF) in 1975 when it was unable to allocate an acceptable daily intake (ADI), but felt able to accept the use of lycopene prepared from natural foods by physical processes, without further investigations, as a coloring matter in food, provided that the amount consumed does not differ significantly from the amount consumed through the relevant foodstuffs. This opinion was reiterated by SCF in 1989. When JECFA evaluated lycopene from natural sources in 1977, they postponed a decision because of lack of data. In 1999 the SCF evaluated synthetic lycopene, but the available data were not sufficient to allow for an acceptance. The SCF concluded "The Committee is not able to allocate an ADI and considers its use in food is unacceptable at present." Synthetic lycopene is currently used as food ingredient but is not approved for coloring matters within the European Union and it is considered generally recognized as safe (GRAS) in the United States (GRAS notice No GRN 000119). In Australia and New Zealand, lycopene is permitted for use as a food color in processed foods in accordance with GMP under Schedule 3 of Standard 1.3.1 in the Food Standards Code. In Japan, tomato color, defined as "a substance composed mainly of lycopene obtained from tomato fruits," is permitted for use as a food additive under the Food Sanitation Law.

To summarize, the lycopene from *B. trispora* is considered by the EFSA Panel to be nutritionally equivalent to natural dietary lycopene, but further safety trials are necessary. While the toxicity data on lycopene from *B. trispora* and on lycopene from tomatoes do not give indications for concern, nevertheless these data are limited and do not allow an ADI to be established. The main concern is that the proposed use levels of lycopene from *B. trispora* as a food ingredient may result in a substantial increase in the daily intake of lycopene compared to the intakes solely from natural dietary sources.

Lycopene from *Fusarium sporotrichioides*

The fungus *F. sporotrichioides* has been genetically modified to manufacture lycopene from the cheap corn fiber material, the "leftovers" of making ethanol. Corn fiber is abundant (the US ethanol industry generates 4 million tons annually) and costs about five cents a pound. Distiller's dry grains with solubles (DDGS) could also be used as a substrate. Using a novel, general method for the sequential, directional cloning of multiple DNA sequences, the isoprenoid pathway of the fungus was redirected toward the synthesis of carotenoids. Strong promoter and terminator sequences from the fungus were added to carotenoid biosynthetic genes from the bacterium *Erwinia uredovora*, and the chimeric genes were assembled, introduced in the fungus, and expressed at levels comparable to those observed for endogenous biosynthetic genes. Cultures in laboratory flasks produced 0.5 mg lycopene per gram dry mass within 6 days and this is predicted to increase in the next few years.

Table 3 Comparison of the chemical compositions of synthetic lycopene, lycopene from tomatoes and lycopene from *Blakeslea trispora*

Lycopene	Chemical synthesis (%)	From tomatoes (%)	From <i>Blakeslea</i>
All-trans isomer	>70	94–96	≥90%
5-Cis isomer	<25	3–5	
9-Cis isomer	<1	0–1	1–5%
13-Cis isomer	<1	1	(Total of cis isomers)
Other cis isomers	<3	<1	

Astaxanthin

Astaxanthin (3,3'-dihydroxy- β,β -carotene-4,4'-dione) is widely distributed in nature and is the principal pigment in crustaceans and salmonid fish. The carotenoid imparts distinctive orange-red coloration to the animals and contributes to consumer appeal in the market place. Since animals cannot synthesize carotenoids, the pigments must be supplemented in the feeds of farmed species. Salmon and trout farming is now a huge business and feeding studies have shown that astaxanthin is very effective as a flesh pigments. There are also reports of beneficial actions of astaxanthin for human health, so its use in supplements is of interest.

Astaxanthin from *Xanthophyllomyces dendrorhous*, formerly *Phaffia rhodozyma*

Among the few astaxanthin-producing microorganisms, *X. dendrorhous* is one of the best candidates for commercial production of (3R,3'R)-astaxanthin. Many academic laboratories and several companies have developed processes suitable for industrial production.

Several reports have shown that constituents in the medium, among other environmental factors, affect astaxanthin production in this yeast. The effects of different nutrients on *X. dendrorhous* have generally been studied in media containing complex sources of nutrients such as peptone, malt, and yeast extracts. By-products from agriculture were also tested, such as molasses, enzymic wood hydrolysates, corn wet-milling coproducts, bagasse or raw sugarcane juice, date juice, and grape juice. Although such media are often convenient because they contain all nutrients, they suffer from the disadvantage of being undefined and sometimes variable in composition; this may mask important nutritional effects. For this reason, several studies have yielded results that are difficult to interpret in detail because of inadequate characterization of growth-limiting factors in the media. Thus, in order to elucidate the nature of nutritional effects as far as possible, chemically defined or synthetic media were used by some authors. In one study, 11 strains were assayed for their ability to utilize 99 different compounds as single carbon source. In a second study, carotenoid biosynthesis was increased at low ammonium or phosphate levels and stimulated by citrate. Factorial design and response surface methodology could be used to optimize the astaxanthin production. The optimal conditions stimulating the highest astaxanthin were 19.7°C temperature, 11.25 g L⁻¹ carbon concentration, 6.0 pH, 5% inoculum, and 0.5 g L⁻¹ nitrogen concentration. Under these conditions the astaxanthin content was 8.1 mg L⁻¹. Fermentation strategy also has an impact on growth and carotenoid production of *X. dendrorhous*, as shown with fed-batch (e.g., limiting substrate is fed without diluting the culture) or pH-stat (i.e., a system in which the feed is provided depending on the pH) cultures. The highest biomass obtained was 17.4 g L⁻¹.

A major drawback in the use of *X. dendrorhous* is that disruption of the cell wall of yeast biomass is required before addition to animal diet, to allow intestinal absorption of the pigment. Several chemical, physical, autolytic, and enzymic methods for cell wall disruption have been described, including a two-stage batch fermentation technique. The first stage was for "red yeast" cultivation. The second stage was the mixed fermentation of the yeast and *Bacillus circulans*, a bacterium with a high cell wall lytic activity.

Another starting point in optimization experiments is the generation of mutants, but metabolic engineering of the astaxanthin biosynthetic pathway is now attractive. It should be possible to manage carbon fluxes within the cell and resolve competition between enzymes such as phytoene desaturase and lycopene cyclase.

The case of *X. dendrorhous* (*P. rhodozyma*) is peculiar as hundreds of scientific papers and patents deal with astaxanthin production by this yeast but the process has not been economically efficient up to now. New patents are filed almost each year, with improvement in astaxanthin yield, for example, 3 mg g⁻¹ dry matter in a US Patent. European Union recently decided to invest again in this yeast, with research programs led by Goethe University in Germany or the Royal University of London, United Kingdom (PROCAR, ERA-IB-14-073 project).

Astaxanthin from *Agrobacterium aurantiacum* and other bacteria

Compared to the huge research effort devoted to *X. dendrorhous*, astaxanthin production by *A. aurantiacum* has been investigated to a lesser extent. The first description of astaxanthin biosynthesis in this bacterium was published in 1994. Astaxanthin is one of 10 carotenoids present. The biosynthetic pathway, the influence of growth conditions on carotenoid production, and the occurrence of astaxanthin glucoside were described in two subsequent papers, but commercial processes have not yet been developed.

Numerous screenings have been conducted with the aim of characterizing new biological sources of astaxanthin, and positive targets were isolated such as *P. carotinifaciens* or *Halobacterium salinarum*. The latter is particularly interesting because (1) the extreme NaCl concentrations (about 20%) used in the growth medium prevent contamination with other organisms, so no particular care has to be taken with sterilization; (2) NaCl concentrations under 15% induce bacterial lysis, so that no special cell breakage technique is necessary; and (3) pigments may be extracted directly with sunflower oil instead of organic solvents. This eliminates possible toxicity problems due to trace amounts of acetone or hexane and facilitates pigment assimilation by animals.

Advantages of astaxanthin over other carotenoids

Some of the advantages of astaxanthin over other carotenoids are

- more stable compared to other carotenoids,
- high antioxidant potential (10 times more than β -carotene and 500 times more than α -tocopherol),
- easily cross the blood-brain barrier,
- high tinctorial property.

Astaxanthin is a powerful bioactive antioxidant and has demonstrated efficacy in animal or human models of macular degeneration, a cause of blindness in a large population. It is also helpful in treating Alzheimer's and Parkinson's diseases, and is known to

offer protection against cancer. Astaxanthin has been shown to be a powerful quencher of singlet oxygen as evident from in vitro studies. Astaxanthin has stronger antioxidant activity, 10 times higher than β -carotene and more than 500 times more effective than α -tocopherol; astaxanthin has been proposed to be the super vitamin E. The antioxidant property has been demonstrated in a number of biological membranes, and astaxanthin has preventive effects against aflatoxin B1 carcinogenicity. Astaxanthin also has strong activity as an inhibitor of lipid peroxidation mediated by active forms of oxygen. The strong antioxidative activities of astaxanthin suggest its potential as photoprotectant against UV irradiation, and astaxanthin-containing preparations for prevention of light-induced aging of skin have been developed.

Mammals lack the ability to synthesize astaxanthin, or to convert dietary astaxanthin into vitamin A. Unlike β -carotene, astaxanthin has no provitamin activity in these animals. Astaxanthin has been shown in both in vitro and in a study with human subjects to be effective for the prevention of the oxidation of low-density protein, suggesting that it can be used to prevent arteriosclerosis, coronary artery disease, and ischemic brain development. A number of astaxanthin health products are under study. Studies on rats had shown no toxicity of astaxanthin preparations. Dietary administration of astaxanthin has proved to significantly inhibit carcinogenesis in the mouse urinary bladder, rat oral cavity, and rat colon. In addition it is reported to induce xenobiotic-metabolizing enzymes in rat liver. Astaxanthin has been shown to enhance in vitro antibody production by mouse spleen cells stimulated with sheep red blood cells and in human blood cells in vitro. Furthermore it has not exhibited any mutagenicity in in vitro study at doses up to 14.4 mg day^{-1} for 2 weeks. There was strong evidence to suggest that astaxanthin was shown to modulate the humoral and nonhumoral immune systems. It enhances the release of interleukin-1 and the tumor necrosis factor α in mice, to a greater extent than canthaxanthin or β -carotene and has the highest cytokinin-inducing activity. Astaxanthin has a significant enhancing action on the production of immunoglobulin A, M, and G and on T-helper cell antibody production, even when suboptimal amounts of antigen are present.

Astaxanthin for salmon and trout feeds

The predominant source of carotenoids for salmonids has been synthetic astaxanthin, which has been used for pigmentation for the last 20 years with FDA approval in 1996. Natural sources of astaxanthin for commercially raised salmonids have been utilized including processed crustacean waste from the krill, shrimp, crab, and crawfish. However, crustacean waste products contain high amounts of moisture, ash, and chitin. Another natural source, *P. rhodozyma* (*X. dendrorhous*) requires a large amount of feed for sufficient pigmentation leading to higher ash contents. The efficiency of utilization of dietary astaxanthin using microalgae for flesh pigmentation of Atlantic salmon and rainbow trout has been demonstrated. For salmon, astaxanthin is even considered as a vitamin essential for the proper development and survival of juveniles. In rainbow trout fed with algae up to 6% of the diet, no major effect on growth or mortalities was observed, and it was concluded to be a safe and effective source of pigment. Astaxanthin has been used to enhance the immune response of fish and shrimp for maximum survival and growth. Also, natural microalgal astaxanthin has shown superior bioefficacy over synthetic form. Full approval in Japan has been received as a pigment in feeds and foods; registration for approval is in progress for the United States, the European Community, and Canada. An amount of 25–100 ppm of carotenoids in the final feed has been considered to give desired pigmentation in various salmonid species. However, the livestock feed market for astaxanthin, presently small, will grow to a comparable size as synthetic ones, which is estimated to \$185 million. The largest market for astaxanthin being aquaculture – making up 24% of total global fisheries – production is currently valued at \$35 billion per annum and is expected to grow to \$49 billion by 2010 (the total carotenoid market is planned to reach 1.53 billion USD by 2021).

Astaxanthin for humans

Limited studies have been carried out about dietary astaxanthin intake by humans. In a study, an astaxanthin-containing drink was used to protect low-density lipoprotein (LDL) from oxidation (astaxanthin was administered $3.6\text{--}14.4 \text{ mg day}^{-1}$ over a period of 2 weeks). Progressively slowing down LDL oxidation with increasing doses of astaxanthin was observed, and no ill effects were reported. When 100 mg of synthetic astaxanthin in olive oil-containing meal was given to male volunteers, maximum plasma concentration of 1.24 mg L^{-1} astaxanthin was observed in the first 6 h postprandially. The relative concentration of total astaxanthin in high-density lipoprotein (HDL) decreases compared to the other lipoprotein fractions in the 72-h study. Based on a study conducted with 40 healthy volunteers, the effect of astaxanthin on mammalian muscle function was reported. Volunteers received one capsule of 4 mg astaxanthin each morning along with food. No significant difference was observed between the treatment and placebo group in any physical parameter measured. The effect of dietary astaxanthin on the health of humans as carried out by Aquasearch Inc. on 33 volunteers consuming daily 3.85 mg (low dose) and 19.25 mg (high dose) for a period of 29 days indicated no ill effects or toxicity due to the consumption of astaxanthin as analyzed by medical and clinical parameters. Other scientists suggested that astaxanthin could be useful for prevention and treatment of neuronal damage associated with age-related macular degeneration, and it may also be effective in treating ischemic reperfusion injury, Alzheimer's disease, Parkinson's disease, spinal cord injuries, and other types of central nervous system injuries. Astaxanthin was found to easily cross the blood–brain barrier and did not form crystals in the eye.

Zeaxanthin

Zeaxanthin (β , β -carotene-3,3'-diol) can be used, for example, as an additive in feeds for poultry to intensify the yellow color of the skin or to accentuate the color of the yolk of their eggs. It is also suitable for use as a colorant, for example, in the cosmetics and food industries, and as a health supplement that may help to prevent age-related macular degeneration.

In the mid-1960s, several marine bacteria were isolated that produced zeaxanthin. Cultures of a *Flavobacterium* sp. (ATCC 21588, classified under the accepted taxonomic standards of that time) in a defined nutrient medium containing glucose or sucrose, as carbon source, were able to produce up to 190 mg of zeaxanthin per liter, with a concentration of 16 mg g⁻¹ dried cellular mass. One species, *Flavobacterium multivorum* (ATCC 55238), is currently under investigation in many studies.

Recently, a zeaxanthin-producing "*Flavobacterium*" was reclassified as a new *Paracoccus* species, *Paracoccus zeaxanthinifaciens* and earlier findings that IPP biosynthesis occurs exclusively via the mevalonate pathway were confirmed. A second strain, isolated in a mat from an atoll of French Polynesia, is peculiar as it also produce exopolysaccharides.

Sphingobacterium multivorum, the new name for *F. multivorum*, was recently shown to utilize the alternative deoxyxylulose phosphate (DXP) pathway. A strain was constructed for overproduction of zeaxanthin in industrial quantities.

As more bacteria are examined, the distribution of the mevalonate and DXP pathways will become better defined, thus facilitating the metabolic engineering of microorganisms with improved production of commercially important isoprenoid compounds including carotenoids.

Canthaxanthin

Canthaxanthin (β,β -carotene-4,4'-dione) has been used in aquafeed for many years in order to impart the desired flesh color in farmed salmonids. A *Bradyrhizobium* sp. strain was described as a canthaxanthin producer and the carotenoid gene cluster was fully sequenced. Interest in canthaxanthin is decreasing since the discovery of extreme overdosage, that is, the deposition of minute crystals in the eye, a fact leading to adverse media attention in the past, and some pressure to limit its use in aquafeeds.

A second bacterium under scrutiny for canthaxanthin production is *Haloferax alexandrinus*, which belongs to the extremely halophilic Archaea, chemo-organotrophic organisms that satisfy some of their energy requirements with light. Members of the family Halobacteriaceae are characterized by red-colored cells, the color in most cases being due to the presence of C50-carotenoids (especially bacterioruberins) as the major carotenoids. Some species have been reported to produce C40-carotenoids and ketocarotenoids as minor carotenoids. Recently, the biotechnological potential of these members of the Archaea has increased because of their unique features, which facilitate many industrial procedures. For example, no sterilization is required, because of the extremely high NaCl concentration used in the growth medium (contamination by other organisms is avoided). In addition, no cell-disrupting devices are required, as cells lyse spontaneously in freshwater. A 1 l scale cultivation of the cells in flask cultures (6 days) under nonaseptic conditions produced 3 g dry mass, containing 6 mg total carotenoid, and 2 mg canthaxanthin. Further experiments in a batch fermenter also demonstrated increases in the biomass concentration and carotenoid production.

A third example is *Gordonia jacobea* (CECT 5282), a Gram-positive, catalase-negative, G+C 61% bacterium that was isolated in routine air sampling during screening for microorganisms that produce pink colonies. Analysis of the carotenoid extracts by HPLC-MS revealed that the main pigment in the isolates is canthaxanthin. The low carotenoid content (0.2 mg g⁻¹ dry mass) in the isolate does not support an industrial application, but after several rounds of mutations, a hyperpigmented mutant (MV-26) was isolated, which accumulated six times more canthaxanthin than the wild-type strain. Apart from their high pigment production, the advantages of mutants of this species from the industrial point of view are (1) the optimal temperature for growth and carotenogenesis is 30°C, which is usual in fermentors; (2) the use of glucose, an inexpensive carbon source, for optimal growth and pigmentation; and (3) the fact that >90% of the total pigments can be extracted directly with ethanol, a nontoxic solvent allowed for human and animal feed. Many other culture media were tested, giving canthaxanthin from 1 to 13.4 mg L⁻¹.

Torulene and Thorularhodin

Yeasts in the genus *Rhodotorula* synthesize carotenoids, mainly torulene (3',4'-didehydro- β,ψ -carotene) and torularhodin (3',4'-didehydro- β,ψ -caroten-16-oic acid), accompanied by very small amounts of β -carotene. Most of the research has focused on the species *Rhodotorula glutinis*, but some papers deal with other species such as *Rhodotorula gracilis*, *Rhodotorula rubra*, and *Rhodotorula graminis*.

Feed supplemented with a *Rhodotorula* cell mass has been found to be safe and non-toxic in animals. Its use in the nutrition of laying hens has also been documented. As the β -carotene content in wild strains of *R. glutinis* is low, efforts have been made to increase it through strain improvement, mutation, medium optimization and manipulation of culture conditions (temperature, pH, aeration, and C/N ratio). These studies mainly resulted in an increased yield of torulene and torularhodin, which are of minor interest, though some did succeed in increasing the β -carotene content up to about 70 mg L⁻¹.

Prospects for Carotenoid Production by Genetically Modified Microorganisms

Escherichia coli and Other Hosts

Metabolic engineering is, in a narrow sense, defined as the use of recombinant DNA techniques for the deliberate modification of metabolic networks in living cells to produce desirable chemicals with superior yield and productivity. The traditional assumption was that the most productive hosts would be microbes that naturally synthesize the desired chemicals, but microorganisms that have the ability to produce precursors of the desired chemicals with superior yield and productivity are also considered as suitable hosts.

As a starting point a large number (200) of genes and gene clusters coding for the enzymes of carotenoid biosynthesis have been isolated from various carotenogenic microorganisms and the functions of the genes have been elucidated. Then large range whole genome sequencing arrived and this number increased tremendously.

In bacteria such as *E. coli*, which cannot naturally synthesize carotenoids, carotenoid biosynthesis de novo has been achieved by the introduction of carotenogenic genes. *E. coli* does possess the ability for synthesize other isoprenoid compounds such as dolichols (sugar carrier lipids) and the respiratory quinones. It is thus feasible to direct the carbon flux for the biosynthesis of these isoprenoid compounds partially to the pathway for carotenoid production by the introduction of the carotenogenic genes. For example, plasmids carrying crt genes for the synthesis of lycopene, β -carotene, and zeaxanthin have been constructed and expressed in *E. coli*. Transformants accumulated 0.2–1.3 mg g⁻¹ dry mass of lycopene, β -carotene, and zeaxanthin in the stationary phase. Several intermediates accumulated at the expense of the end product of the pathway. The use of shotgun library clones constructed with *E. coli* chromosomal DNA has revealed that genes not directly involved in the carotenoid biosynthesis pathway are important, such as *appY* that encodes transcriptional regulators related to anaerobic energy metabolism and can increase the lycopene production to 4.7 mg g⁻¹ dry cell mass.

The most important task for biotechnology will be to identify rate-limiting steps or to eliminate regulatory mechanisms in order to enhance further the production of valuable carotenoids. Some stimulating effect has also been reported for *E. coli* strains that overexpress the DXR synthase gene from *Bacillus subtilis* or *Synechococcus leopoliensis*.

Optimization for high-yield carotenoid production should focus on several different aspects (Fig. 4). First, sufficient amounts of endogenous precursors (i.e., substrates for the reactions involved) should be available (e.g., by control of the pyruvate/glyceraldehyde 3-phosphate ratio, a yield of 25 mg lycopene per gram dry mass has been reported). Second, a balanced system of carotenogenic enzymes should be expressed, to enable efficient conversion of precursors without the formation of intermediate metabolite pools. Third, the correct plasmid combination is important to minimize the accumulation of intermediates and to increase the yield of the end product. Last, the host organism should exhibit an active central terpenoid pathway and possess a high storage capacity for carotenoids.

It has also been shown that the edible yeasts *Candida utilis* and *Saccharomyces cerevisiae* acquire the ability to produce carotenoids when the required carotenogenic genes are introduced (same result was observed for the oleaginous yeast *Yarrowia lipolytica*).

Directed Evolution and Combinatorial Biosynthesis

Directed evolution involves the use of rapid molecular manipulations to mutate the target DNA fragment, followed by a selection or screening process to isolate desirable mutants (Schmidt-Dannert et al., 2006). By various directed evolution protocols, several enzymes have been improved or optimized for a specific condition. Directed evolution was applied to geranylgeranyl diphosphate (GGPP) synthase (a rate-controlling enzyme) from *Archaeoglobus fulgidus* to enhance the production of carotenoids in metabolically engineered *E. coli*. The library of mutated genes that was created was transformed into an *E. coli* strain containing the reconstructed isoprenoid pathway and colonies were then color-screened for the increased conversion of glucose into astaxanthin or lycopene. Eight color-enhanced mutants were obtained from over 10,000 colonies. The production of lycopene was increased by about twofold.

Fig. 4 Metabolic engineering of microbial carotenoid production.

A second example deals with the membrane-associated phytoene synthase, which appears to be the major point of control over product diversity. By engineering the phytoene synthase to accept longer diphosphate substrates, variants were produced that can make previously unknown C45 and C50 carotenoid backbones from the appropriate C20 and C25 isoprenyl diphosphate precursors. A C35 carotenoid backbone has also been biosynthesized. Various downstream enzymes (desaturases and cyclases) from the C30 and C40 carotenoid pathways were found to be functional on these unnatural substrates, leading to the production of a series of novel C35, C45, and C50 carotenoids. Thus, it appears that once a carotenoid backbone structure is created, downstream enzymes, either natural or engineered, such as desaturases, cyclases, hydroxylases, and cleavage enzymes, can accept the new substrate, and whole series of novel carotenoids can be produced.

A different approach to expand the recombinant production of known carotenoids and to synthesize new structures is to combine available biosynthetic genes and evolve new enzyme functions through random mutagenesis, recombination (DNA-shuffling), and selection. Prerequisites for this approach are that crt enzymes from different species can function cooperatively in a heterologous host and display enough promiscuity regarding the structure of their substrates. With a few exceptions, such as the zeaxanthin C(5,6) epoxidase gene, almost all cloned carotenoid biosynthetic genes are functionally expressed in *E. coli*. The success of functional color complementation in transgenic *E. coli* for the cloning of a number of carotenoid biosynthesis genes demonstrates that enzymes from phylogenetically distant species can assemble into a functional membrane-bound multienzyme complex through which carotenoid biosynthesis presumably takes place. The enzymes phytoene desaturase (CrtI) and lycopene cyclase (CrtY) have been targeted for evolution in vitro to achieve synthesis of novel carotenoids in *E. coli*. A variant enzyme, a desaturase chimera, efficiently catalyzed the extended desaturation of the linear C40 carotenoid pathway and introduced six rather than four double bonds into phytoene, to favor the production of the fully conjugated carotenoid (3,4,3',4'-tetra-dehydro- ψ , ψ -carotene).

A related strategy is to combine carotenogenic genes from different bacteria that alone normally produce different end products and to express them in a simple *E. coli* host that carries the biosynthetic machinery for phytoene production. In conjunction with the four-step phytoene desaturase that yields lycopene, a five-step desaturase was used to produce 3,4-didehydro- ψ , ψ -carotene. Further diversification of the C40 skeleton using a 1,2-hydrotase and a C-3,4 desaturase yielded a range of carotenoids, including 3,4-didehydro-1,2-dihydro- ψ , ψ -caroten-1-ol, 3,4,3',4'-tetrahydro-1,2,1',2'-tetrahydro- ψ , ψ -carotene-1,1'-diol, and 1',2'-dihydro- β - ψ -caroten-1'-ol.

Concluding Comments

There are several advantages of microorganisms for the study of biosynthesis and function of pigments. Bacteria and fungi offer a tremendous resource in that they produce hundreds to thousands of various pigmented molecules. It is likely that many more natural pigments will be isolated from this biomass (Dufossé, 2016).

Synthetic pigments traditionally used by food or cosmetic processors continue to be utilized with success; however, with the increasing consumer preference for natural food additives, and the surge of the so-called Southampton study which started a worldwide ban on artificial colorants, natural colorants from plants is now a big business and most of the research efforts within the scientific field of colorants are conducted on natural ones. Regarding bacteria, yeast, or fungi (Table 4), despite common belief about the high production cost of fermentation pigments, two initiatives started in Europe these last decades: β -carotene from the filamentous fungi, *B. trispora* (produced by Gist-Brocades, now DSM; approved in 2000 by the EU Scientific Committee on Food Safety) and Arpink Red from *P. oxalicum* (manufactured by Ascolor now Natural Red) (Dufossé et al., 2014). These companies invested a lot of money as any combination of new source and/or new pigment drives a lot of experimental work, process optimization, toxicological studies, regulatory issues, and tremendous paper work. Time will tell whether investment was cost-effective. Another development under process is the production of lycopene using *B. trispora* by Vitatene, a subsidiary of Spanish penicillin firm Antibioticos. Exploration of fungal biodiversity is still going on, with special interest in water-soluble pigments. The case of *X. dendrorhous* (*P. rhodozyma*) is very peculiar as hundreds of scientific papers and patents deal with astaxanthin production using this yeast and the process has not been economically efficient up to now. Microorganisms could either be used for the biosynthesis of "niche" pigments not found in plants, such as aryl carotenoids. Carotenoids play an exceptional role in the fast-growing "over-the-counter (OTC) medicine" and "nutraceutical" sector. Among carotenoids under investigation for coloring or for biological properties, a small number are available from natural extracts or chemical synthesis. The list is rather short compared to the long list of 750 entries in the "Carotenoid Handbook." With imagination, biotechnology could be a solution for providing additional pigments including interesting aryl carotenoids. Isorenieratene (Φ , Φ -carotene), and its monohydroxy and dihydroxy derivatives, can be produced by bacteria, that is, *Brevibacterium linens*, *Streptomyces mediolani*, or *Mycobacterium aurum*.

Research projects mixing molecular biology and pigments were investigated all over the world, and it seems that current productions are not effective in terms of final yield. Nowadays, combinatorial genetic engineering is being addressed, based on an increasing number of known carotenogenic gene sequences. By combining genes, some authors were able to obtain more efficient biosynthesis, or new carotenoids, never described in nature, such as multihydroxylated ones, which could be very efficient as antioxidants.

Table 4 Microbial production of pigments (already in use as natural colorants or with high potential in this field)

Molecule	Color	Microorganism	Status
Ankaflavin	Yellow	<i>Monascus</i> sp. (fungus)	IP
Anthraquinone	Red	<i>Penicillium oxalicum</i> (fungus)	IP

Glossary

Curli A class of thin, irregular, and highly aggregated adhesive surface fibers expressed by *Escherichia coli* and *Salmonella* spp.

Periplasmic chaperones A class of proteins localized within the periplasm of Gram-negative bacteria that facilitates the folding and assembly of pilus subunits, but which are not components of the final pilus structure.

Phase variation Reversible on and off switching of a bacterial phenotype, such as pilus expression.

Pilin Individual protein subunit of a pilus organelle (also known as a fimbrin). Immature pilins, containing leader signal sequences that direct the transport of pilins across the inner membrane of Gram-negative bacteria, are called propilins or prepilins.

sec secretion system A system involving at least seven proteins that mediates translocation of proteins across biological membranes. Proteins are targeted for *sec*-dependent secretion by the presence of an amino acid signal sequence.

Sortase A transpeptidase that 'sorts' proteins containing the motif LPXTG into the cell wall fraction of Gram-positive bacteria by attachment to peptidoglycan.

Type II secretion system A system of protein secretion in which the substrates are already-folded proteins. Type II secretion systems share many features with type IV pilus assembly.

Type III secretion system A *sec*-independent secretion pathway, also known as T3SS. Numerous Gram-negative pathogens utilize T3SS to secrete and inject effector molecules into the cytosol of host eukaryotic cells.

Usher Oligomeric outer-membrane proteins that serve as assembly platforms for some types of pili. Usher proteins can also form channels through which nascent pili are extruded from bacteria.

Abbreviations

AAF	Aggregative adherence fimbria
BfpA	Bundle-forming pilus
CAP	Catabolite activator protein
CFA	Colonization factor I
CS1	Coli surface antigen 1
CTX ϕ	Cholera toxin phage
EPEC	Enteropathogenic <i>E. coli</i>
ETEC	Enterotoxigenic <i>E. coli</i>
IncF1	F1 incompatibility
Lrp	Leucine-responsive regulatory protein
MR	Mannose-resistant
MS	Mannose-sensitive
T3SS	Type III secretion system
T4SS	Type IV secretion systems
TCP	Toxin coregulated pili
TcpA	Toxin coregulated pilus

Defining Statement

Pili, also known as fimbriae, are proteinaceous, filamentous polymeric organelles expressed on the surface of bacteria. They range from a few fractions of a micrometer to >20 μ m in length and vary from <2 to 11 nm in diameter. Their functions include mediation of cell-to-cell interactions, motility, and DNA uptake.

Pili are composed of single or multiple types of protein subunits, called pilins or fimbrins, which are typically arranged in a helical fashion. Pilus architecture varies from thin, twisting thread-like fibers to thick, rigid rods with small axial holes. Thin pili with

[☆]*Change History:* December 2014: XH Yang added a new section on 'Application of Pili in Immunology and Microbiology' and updated the references.

This article is an update of B.K. Dhakal, J.M. Bower, M.A. Mulvey, Pili, Fimbriae, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 470–489.

diameters of 2–3 nm, such as K88 and K99 pili, are sometimes referred to as ‘fibrillae.’ Even thinner fibers (<2 nm), which tend to coil up into a fuzzy adhesive mass on the bacterial surface, are referred to as thin aggregative pili or curli. High-resolution electron microscopy of P, type 1, and S pili of *Escherichia coli*, and *Haemophilus influenzae* pili has revealed that these structures are composite fibers, consisting of a thick pilus rod attached to a thin, short distally located tip fibrillum. Pili are often expressed peritrichously around individual bacteria, but some, such as type IV pili, can be localized to one pole of the bacterium.

Pili are produced by both Gram-negative and Gram-positive bacteria. The numerous types of pili have been ascribed diverse functions in the adaptation, survival, and spread of both pathogenic and commensal bacteria. Pili can act as receptors for bacteriophage, facilitate DNA uptake and transfer (conjugation), and, in at least type IV pili, function in cellular motility. The primary function of most pili, however, is to act as scaffolding for the presentation of specific adhesive moieties. Adhesive pilus subunits (adhesins) are often incorporated as minor components into the tips of pili, but major structural subunits can also function as adhesins. Adhesins can mediate the interaction of bacteria with each other, with inanimate surfaces, and with tissues and cells in susceptible host organisms. The colonization of host tissues by bacterial pathogens typically depends on a stereochemical fit between an adhesin and complementary receptor architecture. Interactions mediated by adhesive pili can facilitate the formation of bacterial communities such as biofilms and are often critical to the successful colonization of host organisms by both commensal and pathogenic bacteria.

Historical Perspective and Classification of Pili

Pili were first noted in early electron microscopic investigations as nonflagellar, filamentous appendages of bacteria. In 1955, Duguid designated these appendages ‘fimbriae’ (plural, from Latin for thread or fiber) and correlated their presence with the ability of *E. coli* to agglutinate red blood cells. Ten years later Brinton introduced the term ‘pilus’ (singular, from Latin for hair) to describe the fibrous structures (F pili) associated with the conjugative transfer of genetic material between bacteria. Since then ‘pilus’ has become a generic term used to describe all types of nonflagellar filamentous appendages, and it is used interchangeably with the term ‘fimbria.’

Historically, pili have been named and grouped based on phenotypic traits, such as adhesive and antigenic properties, distribution among bacterial strains, and microscopic characterizations. In the pioneering work of Duguid and colleagues, pili expressed by different *E. coli* strains were distinguished on the basis of their ability to bind to and agglutinate red blood cells (hemagglutination) in a mannose-sensitive (MS) versus a mannose-resistant (MR) fashion. Pili mediating MS hemagglutination by *E. coli* were designated type 1, and these pili have since been shown to recognize mannose-containing glycoprotein receptors on host eukaryotic cells. Morphologically and functionally homologous type 1 are expressed by many different species of Enterobacteriaceae. Despite their similarities, however, type 1 expressed by the various members of the Enterobacteriaceae family are often antigenically and genetically divergent within their major structural subunits. In contrast to type 1, most other pili so far identified either are nonhemagglutinating or mediate MR hemagglutination. These pili are very diverse and possess a myriad of architectures and different receptor-binding specificities and functions.

Pili were first identified on Gram-positive bacteria in 1968 by electron microscopy of *Corynebacterium renale*. Other *Corynebacterium* spp., and a number of other Gram-positive bacteria that live in the human oral cavity, were also subsequently shown to express pili. In part because of limitations on molecular genetic analysis in Gram-positive bacteria, relatively little has been known about these structures until recently. Since 2005, it has been discovered that three clinically significant Gram-positive pathogens, *Streptococcus pneumoniae*, group A *Streptococcus*, and group B *Streptococcus*, all express pili. Because pili hold promise as vaccine candidates, we can expect an increase in research on pili in Gram-positive bacteria in coming years.

In the more than 50 years since the discovery and initial characterization of pili, substantial advances have been made in our understanding of the genetics, biochemistry, and structural and functional aspects of these organelles. A vast number of distinct pilus structures have been described and new types of pili continue to be identified. Pili are now known to be encoded by virtually all Gram-negative organisms and are some of the best-characterized colonization and virulence factors in bacteria. In this article, we have classified pili expressed by Gram-negative bacteria into six different groups according to the mechanisms by which they are assembled; pili expressed by Gram-positive bacteria are addressed in a separate section. This classification scheme is not all-inclusive, but provides a convenient means for discussing the diverse types of pili, their functions, structures, and assembly. Representatives of various pilus types assembled by the different pathways discussed in the following sections are listed in Table 1.

Chaperone/Usher Pathway

All pilins destined for assembly on the surface of Gram-negative bacteria must be translocated across the inner membrane, through the periplasm, and across the outer membrane. To accomplish these steps, various adhesive organelles in many different bacteria require two specialized assembly proteins: a periplasmic chaperone and an outer-membrane usher. Chaperone/usher assembly pathways are involved in the biogenesis of over 30 different structures, including composite pili, thin fibrillae, and nonfimbrial adhesins. Here, we will focus on the structure and assembly mechanisms of the prototypical P and type 1 pilus chaperone/usher systems.

Table 1 Pilus assembly pathways

Assembly pathway	Structure	Assembly gene products ^a	Organism	Disease(s) associated with pilus expression
Chaperone–usher pathway				
Thick, rigid pili	P pili	PapD/PapC	<i>E. coli</i>	Pyelonephritis/cystitis
	Prs pili	PrsD/PrsC	<i>E. coli</i>	Cystitis
	Type 1	FimC/FimD	<i>E. coli</i>	Cystitis

Molecular Architecture

P and type 1 are both composite structures consisting of a thin fibrillar tip joined end to end to a right-handed helical rod (Figure 1 (a)–1(f)). Chromosomally located gene clusters that are organizationally and functionally homologous encode P and type 1 (Figure 1(g)–1(h)). P pili are encoded by the *pap* (pilus associated with pyelonephritis) gene cluster, whereas type 1 are encoded by the *fim* gene cluster. The P pilus tip is a 2-nm-wide structure composed of a distally located adhesin (PapG), a tip pilin (PapE), and adaptor pilins (PapF and PapK). The PapG adhesin binds to Gal α (1–4)Gal moieties present in the globoseries (GbO4) of glycolipids found on the surface of erythrocytes and kidney cells. Consistent with this binding specificity, P pili are major virulence factors associated with pyelonephritis caused by uropathogenic *E. coli*. The minor pilin PapF is considered to join the PapG adhesin to the tip fibrillum, the bulk of which is made up of a polymer of PapE subunits. PapK is believed to terminate the growth of the PapE polymer and to join the tip structure to the rod. The pilus rod is composed of multiple PapA subunits joined end to end and then coiled into a right-handed, 6.8-nm-thick helical rod, having a pitch distance of 24.9 Å and 3.28 subunits per turn. The rod is terminated by a minor subunit, PapH, which may serve to anchor the pilus in the membrane.

Similar to the P pilus structure, the type 1 pilus has a short, 3-nm-wide fibrillar tip made up of the mannose-binding adhesin, FimH, and two additional pilins, FimG and FimF. The FimH adhesin mediates attachment to mannosylated receptors expressed on a wide variety of cell types and has been shown to be a significant virulence determinant for the development of cystitis. Like other pilus-associated adhesins, FimH has two distinct domains, a C-terminal pilin domain that links the adhesin to the pilus and an N-terminal receptor-binding or lectin domain (Figure 2). The adhesin domain of FimH is an elongated 11-stranded β -barrel with an overall jellyroll-like topology and a tip-localized mannose-binding pocket. The type 1 tip fibrillum is joined to a rod comprising

Figure 1 P and type 1 architecture and genetic organization. (a) High-resolution electron micrograph of *Escherichia coli* expressing P pili. The inset shows a negatively stained P-piliated *E. coli* bacterium as seen by standard transmission electron microscopy. (b) The tip fibrillum structure of a P pilus. (c) P pili are able to unravel into linear fibers, a phenomenon that may help prevent their breakage under high shearing forces or other stresses. (d) *E. coli* expressing type 1. (e) A high-resolution view of the type 1 pilus tip fibrillum, and (f) a three-dimensional reconstruction of a type 1 pilus rod. The images shown are at different magnifications. The P (*pap*) and type 1 (*fim*) pilus gene clusters are depicted in (g) and (h), respectively. These gene clusters share organizational as well as functional homologies. Photos in (d) and (f) were provided by G. Capitani (Capitani G, Eidam O, Glockshuber R, and Grütter MG (2006). *Microbes and Infection* 8: 2284–2290) and S. Müller (Hahn E, Wild P, Hermanns U, Sebbel P, Glockshuber R, Hänner M, Taschner N, Burkhard P, Aebi U, and Müller SA (2002). *Journal of Molecular Biology* 323: 845–857), respectively, with permission from Elsevier Ltd.

Figure 2 Structure of the type 1 pilus adhesin FimH. Shown on the left is a ribbon model of the FimH adhesin, consisting of two distinct domains. The pilin domain has an immunoglobulin-like fold and allows for incorporation of FimH into the pilus tip. The adhesin domain consists of an 11-stranded β -barrel with an interrupted jellyroll-like motif. This domain is about 50 Å in length and has a distally localized pocket that binds D-mannose (red). A surface model of the mannose-binding pocket of FimH, with bound D-mannose (red), is shown on the right.

predominantly of 500–3000 FimA subunits arranged in a 6- to 7-nm-diameter helix with a pitch distance of 23.1 Å and 3.4 subunits per turn. Both type 1 and P pilus rods have central axial holes with diameters of 2–2.5 and 1.5 Å, respectively. Despite architectural similarities, type 1 appear to be more rigid and prone to breaking than P pili.

In both P and type 1, the major pilin subunits comprising the rods are organized in a head-to-tail manner. Additional quaternary interactions between subunits in adjacent turns of the helical rod appear to stabilize the structure and may help drive the outward growth of the organelle during pilus assembly (see below). Disruption of the latter interactions by mechanical stress or by incubation in 50% glycerol can cause the pilus rod to reversibly unwind into a 2-nm-thick linear fiber similar in appearance to the tip fibrillum (Figure 1(c)). It has been proposed that the ability of the pilus rods to unwind allows them to support tension over a broader range of lengths. This may help P and type 1 better withstand stress, such as shearing forces from the bulk flow of fluid through the urinary tract, without breaking. Type 1 are able to helically unwind and thereby resist breakage under forces up to 60 pN, which is equivalent to the weight of about 60 red blood cells.

In addition to composite structures exemplified by P and type 1, chaperone–usher pathways also mediate assembly of thin fibrillae such as K88 and K99 pili and nonfimbrial adhesins. K88 and K99 pili are 2- to 4-nm-thick fibers that mediate adherence to receptors on intestinal cells. They are significant virulence factors expressed by enterotoxigenic *E. coli* (ETEC) strains that cause diarrheal diseases in livestock. These pili were given the ‘K’ designation after being mistakenly identified as K antigens in *E. coli*. In contrast to P and type 1, the adhesive properties of K88 and K99 pili are associated with the major pilus subunits. The receptor-binding epitopes on the individual major pilus subunits are exposed on the pilus surface and are available for multiple interactions with the host tissue. In general, pili with adhesive major subunits, such as K88 and K99 pili, are thin, flexible fibrillar structures. In comparison, pili with specialized adhesive tip structures, such as P and type 1, are relatively rigid and rod-like.

Assembly Model

The assembly of P pili by the chaperone/usher pathway is among the best understood of any pilus assembly pathway. PapD is the periplasmic chaperone and PapC is the outer-membrane usher for the P pilus system. These proteins are prototypical representatives of the periplasmic chaperone and outer-membrane usher protein families. Figure 3 presents the current model for pilus assembly by the chaperone/usher pathway, as depicted for P pili.

Periplasmic chaperones

The PapD chaperone, the outer-membrane PapC usher, and all of the P pilus structural subunits have typical signal sequences recognized by the *sec* (general secretion) system. The signal sequences are short, mostly hydrophobic N-terminal motifs that tag proteins for transport across the inner membrane by the *sec* system. This system includes several inner-membrane proteins (SecD-G,

Figure 3 Model of P pilus assembly by the chaperone/usher pathway. Structural subunits for the pilus tip (PapG, PapF, PapE, and PapK) and for the pilus rod (PapA) are translocated across the inner membrane of *Escherichia coli* via the *sec* system. On the periplasmic side of the inner membrane they interact with the chaperone PapD, which facilitates the folding and release of the subunits from the inner membrane. DsbA is required for the proper folding of both the subunits and the PapD chaperone. In the absence of the PapD chaperone, pilus subunits aggregate and are degraded by the periplasmic protease DegP. Subunit-chaperone complexes are targeted to the outer-membrane usher, PapC, where the chaperone is released and subunit-subunit interactions occur. The PapC usher forms a 2-nm-wide pore through which the assembled pilus structure is extruded as a linear fiber across the outer membrane. Once on the exterior of the cell, the linear PapA polymer forms a thick, right-handed helical rod that is unable to slip back through the usher pore. The formation of the coiled PapA rod is thought to help drive the outward growth of the pilus. OM indicates outer membrane and IM indicates inner membrane.

SecY, and YajC), a cytoplasmic chaperone (SecB) that binds to presecretory target proteins, a cytoplasmic membrane-associated ATPase (SecA) that provides energy for transport, and a periplasmic signal peptidase. As the P pilus structural subunits emerge from the *sec* translocation machinery into the periplasm, PapD binds to each subunit, facilitating its release from the inner membrane. Each subunit forms an assembly competent, one-to-one complex with PapD. Proper folding of the subunits requires PapD and involves the action of the periplasmic disulfide bond isomerase DsbA. In the absence of PapD, subunits misfold, aggregate, and are subsequently degraded by the periplasmic protease DegP. The misfolding of P pilus subunits is sensed by the Cpx two-component system in which CpxA is an inner-membrane-bound sensor histidine kinase and CpxR is a DNA-binding response regulator. Activation of the Cpx system in response to misfolded pilin subunits or other types of periplasmic stress inhibits P pilus biosynthesis by downregulating pilin expression.

The three-dimensional crystal structures of both the PapD and FimC chaperones have been solved. Both chaperones consist of two Ig (immunoglobulin)-like domains, each consisting of seven β -sheets, oriented into a boomerang shape such that a subunit-binding cleft is created between the two domains. A conserved internal salt bridge is thought to maintain the two domains of the chaperone in the appropriate orientation. Using genetics, biochemistry, and crystallography, PapD was found to interact with pilus subunits in part by binding to a highly conserved motif present at the C-terminus of all subunits assembled by PapD-like chaperones. The finer details of how PapD-like chaperones interact with pilus subunits were unveiled by determining the crystal structures of the PapD-PapK and the FimC-FimH chaperone-subunit complexes (Figure 4). This work demonstrated that the PapD and FimC chaperones have similar interactions with their respective subunits. Only the PapD-PapK structure is considered here. PapK has a single domain consisting of an Ig fold that lacks the seventh (C-terminal) β -strand that is present in canonical Ig folds. The absence of this strand produces a deep groove along the surface of the pilin subunit and exposes its hydrophobic core. By an interaction known as donor strand complementation, a G_1 β -strand of the PapD chaperone occupies the groove in PapK and completes the Ig fold. This interaction shields the hydrophobic core of PapK and stabilizes immature pilus subunits within the periplasm. Interactions with PapD-like chaperones also accelerate the folding of pilin subunits about 100-fold, allowing for more rapid assembly of pili. The residues that make up the C-terminal groove formed by subunits and bound by PapD-like chaperones have been shown by mutagenesis and, more recently, by crystallographic studies to be involved in subunit-subunit interactions

Figure 4 Ribbon model based on the crystal structure of the PapD periplasmic chaperone (in black) complexed with the PapK pilus subunit (in gray). The G_1 β -strand in domain 1 of PapD completes the Ig fold of the pilin, occupying the groove formed between the A2 and F strands of PapK. This interaction has been termed donor strand complementation. The eight N-terminal amino acids of PapK are disordered in the structure. These residues have been implicated in mediating subunit–subunit interactions within the mature pilus organelle. During pilus biogenesis, the N-terminal strand of a pilin can displace the G_1 β -strand of the chaperone and insert into the C-terminal groove of the neighboring subunit. The mature pilus thus consists of a linear array of canonical Ig domains, each of whose fold is completed by a strand from the neighboring subunit.

within the final pilus structure. Thus, in addition to stabilizing immature pilus subunits, the donor strand complementation interaction also caps one of the interactive surfaces of the subunit and prevents premature oligomerization and aggregation of pilus subunits within the periplasm.

Outer-membrane ushers

Once formed in the periplasm, chaperone–subunit complexes are targeted to the outer-membrane usher where the chaperone is released, exposing interactive surfaces on the subunits that facilitate their assembly into the pilus. Studies in the P and type 1 pilus systems have demonstrated that the adhesin–chaperone complexes, PapDG or FimCH, bind tightest and fastest to the usher and that the adhesins are the first subunits assembled into the pilus. Binding of the chaperone–adhesin complex induces a conformational change in the usher, possibly priming it for pilus assembly. Additional subunits are incorporated into the pilus depending, in part, upon the kinetics with which they are partitioned to the usher in complex with the chaperone. Conserved N-terminal regions, in addition to the conserved C-terminal motif of the pilus subunits, mediate subunit–subunit interactions within the mature pilus. Differences in the complementary surfaces in these conserved regions from one subunit to another may help dictate which of the subunits can be joined to one another during pilus assembly. Thus, the order of the subunits within the final pilus structure is determined by the specific contacts made between the different pilus subunits and also by the differential affinities of the various chaperone–subunit complexes for the usher.

In addition to acting as an assembly platform for the growing pilus, the usher protein appears to have additional roles in pilus biogenesis. High-resolution electron microscopy revealed that the PapC usher is assembled into an oligomeric 15-nm-diameter ring-shaped complex with a 2-nm-wide central pore. Each PapC monomer is composed predominantly of transmembrane β -sheets, typical of outer-membrane pore-forming proteins. The N-terminal domain of PapC binds chaperone–complexed subunits, whereas the C-terminal domain stabilizes the chaperone–subunit complexes and is involved in subsequent stages during pilus assembly. Oligomerization of the usher and subsequent pilus biogenesis are both initiated by interactions between the adhesin and the usher. During assembly of type 1, the FimD usher directs the receptor-binding domain of the FimH adhesin into the pore of the usher, whereas the pilin domain remains bound to the chaperone until displaced by the next incoming chaperone–subunit complex. After dissociating from the chaperone at the usher, subunits are incorporated into a growing pilus structure that is predicted to be extruded as a 1-subunit-thick linear fiber through the central pore of the usher complex. Packaging of the linear pilus fiber into a thicker, helical rod on the outside surface of the bacterium may provide a driving force for the translocation of the pilus across the outer membrane, possibly acting as a sort of ratcheting mechanism to force the pilus to grow outward. Combined with the targeting affinities of the chaperone–subunit complexes for the usher and the binding specificities of the subunits for each other, this may provide all the energy and specificity needed for the ordered assembly and translocation of pili across the outer membrane.

Alternate Chaperone Pathway

A variation of the chaperone/usher pilus assembly pathway has been identified in strains of ETEC and a few other pathogenic bacteria. ETEC are major pathogens associated with diarrheal diseases of travelers, infants, and young children. Strains of ETEC produce several types of uniquely assembled adhesive pili that are considered to be important mediators of bacterial colonization of the intestine. The best studied of these pili is coli surface antigen 1 (CS1), which appears to be composed predominantly of a major subunit, CooA, with a distally located minor component, CooD, that is required for ETEC adherence to host cells. Several CS1-like

pili have been identified and include CS2, CS4, CS14, CS17, CS19, CFA/I (colonization factor I, expressed by various ETEC strains), Tcf (expressed by *Salmonella enterica* serovar Typhi), and the cable type II pili of *Burkholderia cepacia*, an opportunistic pathogen of cystic fibrosis patients. Four linked genes, *CooA*, *CooB*, *CooC*, and *CooD*, are the only specific genes required for the synthesis of functional CS1. Electron microscopic examination reveals that the CS1-like pili are architecturally similar to P and type 1 assembled by the chaperone/usher pathway (Figure 5(a) and 5(b)), although none of the proteins involved in the biogenesis of CS1-like pili have any significant sequence homologies to those of any other pilus system.

The assembly of CS1-like pili is functionally similar to that of P pili but depends on a specialized set of periplasmic chaperones that are distinct from those of the chaperone/usher pathway described above. Therefore, this mode of pilus assembly is referred to as the alternate chaperone pathway. In the case of CS1 the chaperone CooB binds to and stabilizes the major and minor pilin subunits, CooA and CooD, which enter into the periplasm in a *sec*-dependent fashion (Figure 5(c)). Both CooA and CooD share a conserved sequence motif near their C-termini that may function as a chaperone recognition motif. One of the functions of CooB appears to be the delivery of the pilin subunits to an outer-membrane protein, CooC, which may function as a channel, or usher, for the assembly of pilus fibers. In addition to the pilin subunits, CooB also binds to and stabilizes CooC in the outer membrane. In the absence of the CooB chaperone, CooC and the pilin subunits are degraded. The minor subunit CooD localizes to the tip of the CS1 pilus and is required for secretion of the major pilus subunit CooA. Expression of CooD also seems to positively regulate the number of pili produced, in keeping with a model in which the positioning of a minor tip subunit (CooD in this case) by an outer-membrane usher complex is required to initiate assembly of the pilus shaft. As CS1-like pili do not appear to be related to those assembled by the chaperone/usher pathway, it has been suggested that these two pilus assembly systems arose independently through convergent evolution.

Type II Secretion Pathway for Type IV Pilus Assembly

Type IV pili are multifunctional, strong, and flexible filamentous structures expressed by a wide diversity of bacteria, including a number of animal and plant pathogens. These include *Pseudomonas aeruginosa*, *Pseudomonas stutzeri*, *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *Eikenella corrodens*, *Legionella pneumophila*, *Ralstonia solanacearum*, *Myxococcus xanthus*, *Francisella novicida*, *Francisella tularensis*, *Dichelobacter nodosus*, *Synechocystis* spp., *Moraxella* spp., and *Azoarcus* spp. Type IV pili can promote bacterial survival and pathogenesis by mediating bacterial interactions with animal, plant, and fungal cells, in some cases contributing to bacterial invasion of target host cells. In addition, these pili can modulate target cell specificity, function in DNA uptake, promote bacterial autoaggregation and biofilm formation, and act as receptors for bacteriophage. Type IV pili are also associated with a flagella-independent form of bacterial locomotion called twitching motility (also known as social motility in *Myxococcus* spp.) that allows for the lateral spread of bacteria across a surface.

Type IV pili are 6 nm in diameter and can extend up to several micrometers in length. These pili are typically assembled at one pole of the bacterium and can withstand forces up to 100 pN. Based on the length and amino acid sequence of the pilin subunits, type IV pili can be divided into two subclasses: type IVa and type IVb. Type IVa pilin subunits are usually composed of 145–160 amino acids. These subunits have several distinctive features, including a short (5–6 amino acids), positively charged leader

Figure 5 Pili assembled by the alternate chaperone pathway. Transmission electron micrographs show (a) CS2 pili (~2 nm thick) assembled by the alternate chaperone pathway in *Escherichia coli* (photo courtesy of Harry Sakellaris and June R. Scott) and (b) Cbl pili of *Burkholderia cepacia*. Reproduced from Sajjan US, Sun L, Goldstein R, and Forstner JF (1995). *Journal of Bacteriology* 177: 1030–1038, with permission from ASM press. (c) Assembly of CS1 from *E. coli* via the alternate chaperone pathway. The CooB chaperone forms periplasmic complexes with the main components of the pilus, CooA and CooD. CooB also appears to bind and stabilize the outer-membrane protein CooC during pilus assembly. CooC functions as an outer-membrane (OM) channel for passage of the pilin fiber.

sequence that is cleaved during assembly, *N*-methyl-phenylalanine as the first residue of the mature subunit, and a highly conserved, hydrophobic N-terminal domain that forms the core of the mature pilus.

Type IVb pili include the toxin coregulated pilus (TcpA) of *Vibrio cholera*, bundle-forming pilus (BfpA) of enteropathogenic *E. coli* (EPEC), longus (LngA) and CFA/III pili of ETEC, conjugative R64 thin pilus of *E. coli*, and colonization factor Citrobacter (CfcA) of *Citrobacter rodentium*. In contrast to type IVa pilins described above, the known type IVb pilins are somewhat larger (180–238 amino acids) and have a longer (15–30 amino acids) leader sequence. Also, in place of *N*-methyl-phenylalanine as the first amino acid in the mature pilus subunit, type IVb subunits have other methylated residues such as *N*-methyl-methionine for TcpA and *N*-methyl-leucine for BfpA. TCP, BFP, and longus pili form large polar bundles over 15 μm in length. In contrast, CFA/III pili are 1–10 μm long and are peritrichously expressed.

Atomic resolution structures of the type IVa pilins Pile (*N. gonorrhoeae*) and PilA (*P. aeruginosa* strains K and K122-4), as well as the type IVb pilin TcpA (*V. cholera*), have been solved (Figures 6 and 7). Based on these structures, all type IV pilin subunits are predicted to have a fairly similar structure consisting of a conserved N-terminal α -helical hydrophobic core surrounded by β -sheets and a hypervariable C-terminus. The core α -helix of type IV pilins, known as $\alpha 1$ (blue in Figure 6), is usually composed of 53 amino acids and is divided into a protruding hydrophobic N-terminal half ($\alpha 1$ -N, residues 1–29) and an amphipathic C-terminal half ($\alpha 1$ -C, residues 30–53). The hydrophobic face of $\alpha 1$ -C is wrapped by antiparallel β -sheets to form a globular head domain, whereas the hydrophilic face is buried within the assembled pilus. This hydrophobic packing of the inner core of α -helices along with the flexibility of these helices may permit type IV pili to bend and adopt twisted, bundled conformations (Figure 7). Hydrogen bonds throughout the layer of β -sheets may provide much of the mechanical stability for the pilus.

Type IV pilin globular head domain (green in Figure 6) is flanked by two highly variable regions designated the $\alpha\beta$ -loop (orange in Figure 6) and D-region (yellow in Figure 6). The $\alpha\beta$ -loop functions as a linker between the $\alpha 1$ and the β -sheets, and facilitates pilin–pilin interactions before and after assembly. The D-region contains a conserved disulfide bridge, which is essential for pilus assembly. These hypervariable regions associate with the layer of β -sheets through only a few conserved interactions. Thus, they can be structurally pliant and accommodate extreme amino acid changes that lead to antigenic variation and altered binding specificities without disrupting the assembly of the pilus. The antigenic characteristics of type IV pili synthesized by *N. gonorrhoeae* can be modified extensively by a remarkable mechanism. This pathogen encodes more than 15 different silent pilin genes termed PilS that lack the invariant N-terminal domain present in Pile. By recombination of silent PilS genes with the Pile locus, a single neisserial strain can theoretically express more than 10 million Pile variants. This antigenic variation helps *N. gonorrhoeae* evade the host immune system, allowing the establishment and maintenance of infection.

Figure 6 Ribbon model of the type IVa pilin, Pile, from *Neisseria gonorrhoeae*. Secondary structural elements include a hydrophobic core surrounded by β -sheets (green), a conserved N-terminal α -helical spine (blue) connected to a variable domain containing an $\alpha\beta$ -loop (orange) with an O-linked disaccharide at Ser-63 and a disulfide-containing C-terminal D-region (yellow). The conserved disulfide bridge in the D-region is signified by a dotted line (magenta).

(b) Three-dimensional reconstruction of type IV pilus rod, which is made up of repeating and overlapping PilE pilin subunits. (c) Localization of a single PilE subunit (yellow) within the pilus rod. Image courtesy of L. Craig and C. Brinton (Craig L, Volkmann N, Arvai AS, Pique ME, Yeager M, Egelman EH, and Tainer JA (2006). *Molecular Cell* 23: 651–662), with permission from Elsevier Ltd. (d) Model of type IV pilus assembly by *N. gonorrhoeae*. The PilE prepilin is translocated into the periplasm aided by the *sec* machinery. PilE is processed by the PilD signal peptidase, which cleaves the positively charged leader sequence from the N-terminus of the pilin subunit. An inner-membrane assembly complex then assembles the mature PilE subunit into a pilus fiber. PilQ mediates translocation of the pilus through the outer membrane, possibly with the assistance of other factors such as PilP. PilC associates with the pilus and may act as a restraining clip, preventing PilT-mediated retraction of the type IV pilus rod. The PilC1 adhesin, which appears to be incorporated at the tip of the growing pilus fiber, also seems to be required for translocation of the pilus through the outer membrane.

The biogenesis of type IV pili is substantially more complicated than pilus assembly by the chaperone/usher or alternate chaperone pathways. Most type IVa pili-encoding genes are located on the chromosome, whereas most type IVb pili are encoded by plasmids. The number of genes essential for type IV pilus biogenesis and function ranges from 14, for pili such as BFP, to over 20, for structures such as the type IVa pili of *N. gonorrhoeae*. In *P. aeruginosa*, it is estimated that about 0.5% of the bacterium's genome is involved in the synthesis and function of type IV pili. Among the various bacterial species expressing type IV pili, the genes encoding the type IV pilus structural components tend to be similar, whereas the regulatory components surrounding them are typically less conserved.

Type IV pilus biogenesis occurs in three steps: fiber formation, fiber stabilization, and surface localization of the intact organelle. In the case of *N. gonorrhoeae* pili, the process requires more than 14 assembly proteins and a type II secretion system-related multicomponent assembly complex. Components include a prepilin peptidase (PilD) that cleaves off the leader peptide from nascent pilin subunits; a polytopic inner-membrane protein that may act as a platform for pilus assembly; a hydrophilic nucleotide-binding protein located in the cytoplasm or associated with the cytoplasmic face of the inner membrane that may provide energy for pilus assembly; and an outer-membrane protein complex (PilQ) that forms a pore for passage of the pilus to the exterior of the bacterium.

The PilE/PilA prepilin subunits are transported into the periplasm by the *sec* translocation machinery (Figure 7(d)). After translocation, the prepilin subunits remain anchored in the inner membrane by their hydrophobic N-terminal α -helical domains, with their hydrophilic C-terminal heads oriented toward the periplasm. Removal of the positively charged prepilin leader sequence by the PilD signal peptidase drives the hydrophobic stems of the pilin subunits to associate and form a pilus. An inner-membrane assembly complex made up of several proteins including PilD, PilF, PilG, and PilT aids in this process. The outer-membrane-associated PilC has been shown to stabilize the nascent pilus before translocation and prevent PilT-mediated retraction. The assembled pilus penetrates the outer membrane through an electrochemically gated oligomeric channel formed by PilQ. The ring-shaped oligomeric channel formed by PilQ has 12-fold symmetry and an internal diameter of 5–7 nm. Its assembly and localization is facilitated and stabilized by small lipoproteins, PilP in *N. gonorrhoeae*, BfpG in EPEC, and Tgl in *M. xanthus*. The PilC1 adhesin associated with the tips of type IV pili in *N. gonorrhoeae* may facilitate passage of the nascent pili through the PilQ pore.

One implication of this assembly model is that the N-terminal region of PilA/PilE resides in a continuous hydrophobic environment during both inner-membrane transport and pilus assembly. This may allow polymerization and, interestingly, depolymerization of the pilus to proceed with only minimal energy requirements. Type IV pili undergo rounds of extension and retraction by polymerization and depolymerization reactions. The nucleotide-binding protein PilB facilitates the polymerization and extension of pili, whereas PilT (a distant member of the AAA ATPase motor family) mediates rapid depolymerization and retraction, at rates up to 1500 pilin subunits per second. These rounds of extension and retraction are the basis of twitching motility, one of the functions of type IV pili. The current model for twitching motility can be compared to the usage of a grappling hook. It involves the extension of a pilus, the adhesion of the pilus tip to a surface, and then the retraction of the pilus to pull the cell forward. The capacity of type IV pili to retract may also provide a means for transforming DNA, which could potentially interact with the type IV pilus, to enter into the bacterial cell. Mutation in components of the type IV pilus PilT in *N. gonorrhoeae* results in the loss of transformability. Naturally competent bacteria such as *Bacillus subtilis*, *H. influenzae*, and *S. pneumoniae* do not have type IV pili, but do have similar components that facilitate the transformation of naked DNA. The adhesive properties of type IV pili are, in general, determined by the major pilus subunit. Additional minor components, however, may associate with these pili and alter

their binding specificities. In the case of *Neisseria*, a tip-localized adhesin, PilC1, appears to mediate bacterial adherence to epithelial cells.

Many of the components involved in type IV pilus assembly share homology with proteins that are part of DNA uptake and protein secretion systems, collectively known as the main terminal branch of the general secretory (*sec*-dependent) pathway, or type II secretion. Type II secretion systems transport a variety of proteins, including toxins, proteases, cellulases, and lipases, from the periplasm to the extracellular space. The pullulanase secretion system in *Klebsiella oxytoca* is a prototypical type II secretion system. Transport of pullulanase (PulA, a starch-hydrolyzing lipoprotein) through the outer-membrane protein complex (PulD) involves four type IV pilin-like proteins, known as pseudopilins. Like type IV pilins, the pseudopilins are processed by a prepilin peptidase; the peptidase is even interchangeable between the two systems. The pseudopilins may assemble into a 'secretion tube' – a pilus-like structure that extends across the periplasm and facilitates PulA transfer to the outer membrane. Pseudopilin filaments have been observed upon overexpression of the pseudopilin genes, but have not yet been demonstrated to exist under normal conditions.

Another structure that is believed to have evolutionary relatedness to type IV pili is the archaeal flagellum. Archaeal flagella are about 10 nm in diameter, and, like bacterial flagella, rotate and switch directions to mediate motility. However, orthologues of bacterial flagellin motor proteins have not been found in any archaeal genome, and the mechanism of rotation and switching in archaea is still unknown. Archaeal flagellar subunits have no similarity to bacterial flagellins, but they are similar to type IV pilins. Like type IV pilins, archaeal flagellins require processing by a signal peptidase before assembly into a filament, and their assembly requires both a nucleotide-binding protein and a polytopic cytoplasmic membrane protein.

Conjugative Pilus Assembly Pathway

In Gram-negative bacteria, certain pili, collectively known as conjugative pili, facilitate the transfer of DNA among bacteria. These pili allow donor and recipient bacteria to make specific and stable intercellular contacts before DNA transfer is initiated. DNA is moved between cells through the mating pair formation system, which is related to the so-called type IV secretion systems (T4SS). Horizontal gene transfer, or conjugation, mediated by conjugative pili is inextricably associated with the spread of antibiotic resistance among bacterial pathogens. Conjugative pili are generally encoded by self-transmissible plasmids that are capable of passing a copy of their genes to a recipient bacterium. Closely related plasmids, with similar replication control systems, are unable to coexist within the same cell. This property has been termed 'incompatibility' and provides the primary basis for cataloguing conjugal plasmids and the pili that they encode. Thus far, in *E. coli* alone, over 25 incompatibility groups composed of well over 100 different plasmids have been defined. Plasmids within a particular incompatibility group usually encode conjugative pili with similar antigenic properties, sensitivities to pilus-specific phage, and morphologies.

Among the multitude of known incompatibility groups, three morphologically and functionally distinct types of conjugative pili have been defined: (1) rigid; (2) thick, flexible; and (3) thin, flexible pili. Rigid conjugative pili are 8- to 11-nm-wide structures that are usually specified by conjugal DNA transfer systems that function well only on solid surfaces. Thick, flexible pili, on the other hand, are 8- to 11-nm-wide structures that typically, but not always, promote conjugation on solid surfaces and in liquid media equally well. Conjugal DNA transfer promoted by rigid or thick, flexible pili can be enhanced, in some cases, by the presence of thin, flexible pili. These pili are similar in appearance to type IV pili and at least one member of the thin, flexible pilus group (the R64 thin pilus) has been identified at the molecular level as a type IVb pilus (as described above). Thin, flexible pili appear to function primarily in the stabilization of bacterial mating pairs, increasing the rate of DNA transfer. Conjugation does not occur in the presence of thin, flexible pili alone or in the absence of rigid or thick, flexible pili.

The most thoroughly studied conjugative pilus is the F pilus encoded by the self-transmissible, broad host range F (fertility) plasmid, a member of the F1 incompatibility (IncF1) group of plasmids borne by *E. coli*. The F pilus system is prototypical for numerous other conjugation systems, and F pilus biogenesis is distinct from type IV and other pilus assembly pathways. F pili are 8-nm-thick, flexible helical filaments that consists primarily, if not completely, of repeating 7.2 kDa (70 amino acid) TraA pilin subunits. Donor (F⁺) cells typically express 1–3 F pili that are usually 1–2 μ m long. Each F pilus possesses a 2-nm-wide central channel that is lined by basic, hydrophilic residues, which could potentially interact with negatively charged DNA or RNA molecules during conjugation. TraA is organized into pentameric, doughnut-like disks that are stacked within the pilus such that successive disks are translated 1.28 nm along the pilus axis and rotated 28.8° with respect to the lower disk. The TraA pilin has two hydrophobic domains located toward the center and at the C-terminus of the pilin. The hydrophobic domains are thought to extend as antiparallel α -helices from the central axis to the periphery of the pilus shaft. These domains are separated by a short, basic region that appears to form the hydrophilic wall of the central channel of the pilus. The N-terminal domain of TraA is predicted to face the exterior of the pilus. However, this domain is antigenically masked when the N-terminal residue of TraA is acetylated during maturation of the pilin (see below). This modification is common among all known F-like pilins and appears to cause the N-terminal domain to be tucked back into or along the pilus shaft. Acetylation is not essential for F pilus assembly or function, but does help prevent aggregation of F-like pili and affects the phage-binding characteristics of these organelles. Phage are also known to recognize the C-terminal hydrophobic domain of TraA. Although masked within the pilus shaft, the acetylated N-terminal domain of TraA appears to be exposed in unassembled pilin subunits and at the distal tips of pili. The F pilus tip is believed to initiate contact between donor and recipient cells during conjugation and serves as a receptor for F-specific filamentous phage. Alterations in the N-terminal sequence of pilin subunits provide the primary basis for the antigenic diversity observed among F-like pili expressed by plasmids F, R1-19, ColB2, pED208, and R100-1.

A number of genes encoded by the F plasmid *tra* operon are required for conjugation. TraA is synthesized as a 12.8 kDa (121 amino acids) cytoplasmic propilin, but is processed into a 7.2 kDa pilin form by host signal peptidase LepB in the periplasm. Pilin maturation gene products TraQ and TraX mediate the processing of the TraA pilin to its mature form. TraQ, a chaperone-like inner-membrane protein, escorts TraA into the inner membrane and helps position the TraA propilin for processing into mature pilin. In the absence of TraQ, the translocation of TraA is disrupted and most of the pilin subunits are degraded. After processing, the N-terminal residue (alanine) of TraA is acetylated by TraX, a polytopic inner-membrane protein. The core T4SS proteins, TraB, TraC, TraE, TraG, TraK, TraL, and TraV, are involved in both pilus assembly and DNA transport. Additional gene products (TraW, TraN, TraU, TraF, TraH, TrbC, and TrbI) affect the assembly of TraA into the pilus filament. Most of these proteins appear to associate with either the inner or outer bacterial membrane and may constitute a pilus assembly complex that spans the periplasmic space.

The exact mechanism by which TraA is assembled into pili is not yet defined. Pools of up to ~100 000 mature TraA pilins accumulate in the inner membrane before pilus assembly, which appears to occur by addition of pilin subunits at the base of the growing pilus. Both hydrophobic domains of TraA span the inner membrane, with the hydrophilic region of TraA connecting them on the cytoplasmic side. Small clusters of TraA also accumulate in the outer membrane and these may function as intermediates in F pilus assembly and disassembly. Large regions of the TraA sequence have the propensity to assume both β -sheet and α -helical structures, although the α -helical conformation is known to predominate in assembled pili. It has been suggested that a shift between β -sheet and α -helical conformations drives pilus assembly and disassembly. F pilus assembly is energy dependent and the depletion of ATP levels by respiratory poisons such as cyanide results in F pilus depolymerization and retraction. It is possible that TraA is normally cycled between pili and periplasmic/inner-membrane pools by rounds of pilus outgrowth and subsequent retraction. During conjugation, F pilus retraction is believed to serve a stabilizing function by shortening the distance between bacterial mating pairs and allowing for more intimate contact.

Several components of the F pilus assembly machinery share significant homology with proteins encoded by other conjugative systems. These include proteins specified by broad host range plasmids in other incompatibility groups (such as IncN, IncP, and IncW) and many of the proteins encoded by the Ti (tumor inducing) or Ri (root inducing) plasmid-specific *vir* genes of the plant pathogens, *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes*, respectively. These bacteria elaborate 10-nm-wide promiscuous conjugative pili, called T pili, at one end of a cell that direct the interkingdom transfer of a specific genetic element, known as T-DNA, into plant and yeast cells. The introduction of T-DNA into plant cells induces plant tumor formation. The exact mechanism of T-DNA transfer is not known, but the T pilus is essential for T-DNA transfer. T pili may facilitate direct cell-to-cell contact for T-DNA transfer, possibly providing a conduit for passage of T-DNA. In addition, the T pilus could act as a sensor, allowing infecting bacteria to receive signals from the host plant. T pilus assembly by *A. tumefaciens* requires the expression of at least 12 *vir* gene products encoded by the Ti plasmid. VirB2 is the major, and possibly only, component of the T pilus and it is predicted to be structurally homologous to the F pilus subunit TraA. Unlike F pili, T pili do not retract, but instead wind together to form very compact coils, bringing the surface of bacterium and the host closer (Figure 8).

Other than possibly stabilizing donor-recipient interactions, it is not yet clear as to how F and T pili or any pilus structures function in conjugative DNA transfer processes. However, at least in F pili, substantial evidence suggests that pilus components or the pilus itself can serve as a specialized channel for the transmission of DNA and any accompanying pilot proteins across the donor and possibly the recipient cell membranes. In light of this possibility, it is interesting to note that many components of the conjugative pilus systems encoded by the IncF, IncN, IncP, and IncW plasmids and by the *vir* genes of *A. tumefaciens* are similar to the Ptl proteins responsible for the export of the multiple subunit toxin of *Bordetella pertussis*. Interestingly, in *Brucella suis* and *Bartonella henselae*, *virB* homologues are arranged in the same order as in the *A. tumefaciens virB* operon. Furthermore, these secretion systems seem to be distantly related to transport systems used by *L. pneumophila*, *Helicobacter pylori*, and *Rickettsia prowazekii* to inject virulence factors into host eukaryotic cells. Conjugative pilus systems such as those encoding F and T pili thus appear to be representative of a larger family of macromolecular transport systems. These so-called type IV secretion systems represent a major pathway for the transfer of both nucleic acid and proteins between cells. Understanding how conjugative pili help mediate the intercellular transfer of macromolecules remains a significant challenge.

Extracellular Nucleation/Precipitation Pathway

Many strains of enteric bacteria, including *E. coli* and *Salmonella* species, produce a class of thin (<2 nm), irregular, and highly aggregated surface fibers known as curli (Figure 9(a) and 9(b)). Curli are described as amyloid-like fibers, and are composed mainly of extracellular matrix components, namely protein, cellulose, and an unknown polysaccharide. They are highly stable structures and extreme chemical treatments are required to depolymerize them. The major component of *E. coli* curli is a 15.3 kDa protein known as CsgA, which shares over 86% primary sequence similarity to its counterpart in *S. enterica* ser. Typhimurium, AgfA.

The formation of curli represents a departure from the other modes of pilus assembly discussed in the previous sections. Whereas structures exemplified by P, CS1, type IV, and F pili are assembled from the base, curli formation occurs on the outer surface of the bacterium by the precipitation of secreted soluble pilin subunits into thin fibers (Figure 9). In *E. coli*, the products of two divergently transcribed operons are required for curli assembly. The *csgBA* operon encodes the primary fiber-forming subunit, CsgA, which is secreted as an unpolymerized protein directly into the extracellular environment. The second protein encoded by the *csgBA* operon, CsgB, is proposed to induce polymerization of CsgA at the cell surface. In support of this model, by interbacterial complementation it has been demonstrated that a CsgA⁺CsgB⁻ donor strain can secrete CsgA subunits that can be assembled into curli on the surface of a CsgA⁻CsgB⁺ recipient strain. In the absence of CsgA, overexpressed CsgB is able to form short polymers on the bacterial cell surface.

The *csgDEFG* operon encodes a gene for a transcriptional activator of curli synthesis (CsgD), and three genes encoding putative assembly factors. One of these factors, CsgG, has recently been shown to be a lipoprotein that is localized to the outer membrane. In the absence of CsgG, curli assembly does not take place, and CsgA and CsgB are rapidly degraded. The precise role of CsgG is not known at this time. It has been suggested that CsgG might act as a chaperone that facilitates the secretion of the CsgA and CsgB and protects them from degradation within the periplasm. It is also possible that CsgG assembles into oligomeric, ring-shaped complexes that could function as a Csg-specific channel within the outer membrane. It has been reported that a strain lacking CsgE is defective in curli assembly, as the stability of both CsgA and CsgB in this mutant background is greatly reduced. Mutation of *csgF* does not affect CsgA secretion, but CsgA made by *csgF* mutants does not polymerize. Environmental factors such as very low salt concentrations, nutrient limitation, microaerophilic conditions, and temperatures below 30 °C favor maximal curli gene expression. RpoS, a stationary-phase sigma factor; OmpR/EnvZ, a two-component regulatory system; and IHF, a global regulatory protein all positively regulate curli expression. Two other two-component regulatory systems, CpxA/R and Rcs, negatively regulate curli expression. Interestingly, histone-like protein HN-S positively regulates curli expression in *S. enterica* ser. Typhimurium, but negatively regulates it in *E. coli*.

Figure 9 Curli assembly by an extracellular nucleation/precipitation pathway. (a) Electron micrographs of negatively stained *Escherichia coli* expressing curli. (b) High-resolution electron micrograph, obtained using a deep-etch technique, of purified curli. Photo courtesy of M. Chapman (Barnhart MM and Chapman MR (2006). *Annual Review of Microbiology* 60: 131–147), with permission from Annual Reviews. (c) Model of curli assembly by the extracellular nucleation/precipitation pathway. CsgA, the main component of curli from *E. coli*, is secreted across the outer membrane. CsgB serves to nucleate CsgA assembly. CsgG is an outer-membrane-localized lipoprotein that is required for the secretion of CsgA and CsgB, although its function is not yet entirely clear. CsgE and CsgF are periplasmic proteins that interact with CsgG at the outer membrane.

Curli promote bacterial adherence to host cells and tissues by binding to a variety of host proteins, including plasminogen, fibronectin, and human contact phase proteins. Interestingly, curli are recognized as a pathogen-associated molecular pattern by host Toll-like receptor 2, a component of the innate immune system that can recognize incoming pathogens and induce robust proinflammatory responses. Curli are also involved in bacterial colonization of inert surfaces, and have been implicated in cell aggregation and biofilm formation.

Type III Secretion Pathway

The various pilus assembly pathways described in the previous sections all rely on components of the *sec* machinery for the translocation of their respective pilus subunits across the inner membrane. Other types of pili are assembled by a *sec*-independent pathway known as the type III secretion system (T3SS). The T3SS is encoded by numerous Gram-negative pathogens and enables these bacteria to secrete and inject pathogenic effector molecules into the cytosol of eukaryotic host cells. About 20 gene products, most of which are inner-membrane proteins, comprise the T3SS. The components mediating type III secretion are conserved in pathogens as diverse as *Yersinia* and *Erwinia*, but the secreted effector proteins vary significantly between species. The T3SS apparatus, which appears to span the periplasmic space, resembles the basal body of a flagellum connected to a straight rod that extends across the outer membrane. Interestingly, all T3SS encode some components with homologies to proteins involved in flagellar assembly. The secretion of proteins by the T3SS is an ATP-dependent process that involves no distinct periplasmic intermediates. Type III-secreted proteins of EPEC, the nodule-forming strains of *Rhizobium* species and *Sinorhizobium fredii*, and several plant pathogens including *Pseudomonas syringae* pathovar tomato, *Erwinia amylovora*, *R. solanacearum*, and *Xanthomonas campestris* have been shown to assemble into pilus-like structures.

EPEC encodes four proteins, EspA, EspB, EspD, and Tir, which are secreted by a type III pathway. These proteins facilitate intimate contact between the pathogen and host intestinal cells and are required for the formation of specific (attaching and effacing) lesions. In 1998, Knutton and colleagues showed that one of these proteins, EspA, can assemble into 10- to 12-nm-thick peritrichously expressed pilus-like fibers that are organized into ~50-nm-wide bundles and extend up to 2 μ m from the bacterial surface (Figure 10 (a) and 10(b)). The assembly of these EspA filaments requires several other components of the T3SS, including an outer-membrane secretin called EscC, a type III translocator protein EspD, the T3SS ATPase EscN, and EscF, the major structural protein of the T3SS needle complex. Coiled-coil interactions of EspA polypeptides lead to the assembly of EspA filaments in a process similar to that of flagellar assembly from flagellin subunits. During the infection process, the EspA fibers appear to mediate contact between EPEC and the host cell surface before the establishment of more intimate bacterial attachment. The EspA fibers seem to assist the translocation of EspB and other effector molecules into host cells where they can subvert host signal transduction pathways.

In *P. syringae* and other plant pathogens, T3SS are encoded by *Hrp* and *Hcp* (*hrp* conserved) genes. *Hrp* stands for hypersensitive response and pathogenicity, reflective of these genes' roles in causing disease in susceptible plants and eliciting the hypersensitive response (a rapid, localized host cell death, which limits the spread of a pathogen) in resistant plants. HrpA from *P. syringae* and *E. amylovora*, HrpE from *X. campestris*, and HrpY from *R. solanacearum* have all been shown to be assembled into 6- to 8-nm-wide, 2- μ m-long peritrichously expressed pili (Figure 10(c)). These Hrp pili subunits are small proteins (6–11 kDa) with significant variation in their amino acid sequences, but their assembled pili are remarkably consistent α -helix-rich structures. Assembly of Hrp pili contrasts against all other known pilus assembly systems in that subunits are added at the tip, rather than at the base, of the pilus. The Hrp secretion system is always found at Hrp pilus assembly sites, suggesting that the pili act as a conduit or guiding filament for the delivery of effector proteins into host cells. Hrp pili might also be involved in the penetration of the host plant cell wall, perhaps by pore formation or cell wall modification during effector delivery.

Pili in Gram-Positive Bacteria

Pili have been observed on a number of Gram-positive bacteria, but to date their study is less advanced than that of their Gram-negative counterparts. The best-defined Gram-positive pili are made by *Corynebacterium diphtheriae*, which carries at least three different types, designated SpaA, D, and H after their major subunits. SpaA is considered the prototypical Gram-positive pilus type, and most of the following information (and the model for pilus assembly in Figure 11) is based on findings from *C. diphtheriae* SpaA. It should be noted however that other *Corynebacterium* spp., *Actinomyces* spp., and *Streptococcus* spp. are believed to form pili in a similar manner. In addition, Gram-positive species *Arthrobacter photogonimus* and *Ruminococcus albus* are believed to assemble pili by a separate mechanism(s) that has not yet been elucidated.

Pili on Gram-positive bacteria differ from Gram-negative pili in several important ways. Most notably, while the subunits of Gram-negative pili are held together by noncovalent attachments, Gram-positive pilin subunits attach to each other, and to cell wall peptidoglycan, by covalent bonds. Sortases – transpeptidases named for their role in ‘sorting’ proteins to the cell wall fraction – are required for the formation of these covalent bonds. The SpaA, D, and H pili in *C. diphtheriae* are named for this requirement, where spa stands for sortase-mediated pilus assembly.

Like many Gram-negative pilins, Gram-positive pilus subunits carry N-terminal signal peptide sequences that target them for secretion through the cell membrane by the *sec* machinery. Spa-like pilins also carry crucial residues at the C-terminus: a cell wall-sorting pentapeptide (usually LPXTG), a hydrophobic region of 30–40 amino acids, and a positively charged tail. Upon translocation by the *sec* machinery, the pilin’s hydrophobic region is inserted into the membrane, and held in place by the charged tail. Membrane-associated sortases then cleave the subunit’s recognition peptide, leaving the C-terminus embedded in the membrane while the body of the pilin is attached to the enzyme to form an acyl-enzyme intermediate. Nucleophilic attack by an amino group – on either a peptidoglycan precursor (for joining to the cell wall) or another pilin subunit (for pilus growth) – releases the pilin from the sortase enzyme. This process is depicted in Figure 11.

Spa pili in *C. diphtheriae* are thin fiber-like structures, 2–6 nm in diameter and 0.2–3 µm long. Each pilus is composed primarily of its major subunit, although some also include a tip subunit and other minor subunits along the shaft that are not required for pilus synthesis or integrity. Major pilus subunits contain a conserved pilin motif, which is believed to mediate release of the previous pilin from its sortase by nucleophilic attack. The absence of this motif in tip subunit SpaC may account for its tip-only

Figure 11 Generalized model of pilus assembly in Gram-positive bacteria. SpaA pili are composed of three types of pilins: SpaA, which forms most of the pilus shaft; SpaB, a minor subunit of unknown function not included in this schematic diagram; and SpaC, which is found at the pilus tip. Other Spa-like pili have similar components. The tip protein is probably the first pilin to be incorporated into a new pilus. Upon translocation by the *sec* machinery (mediated by an N-terminal secretion signal), a pilin’s hydrophobic region is inserted into the membrane and held in place by a positively charged tail. A membrane-associated sortase then cleaves the subunit’s recognition peptide (usually LPXTG), leaving the C-terminus embedded in the membrane while the main body of the pilin is attached to the enzyme to form an acyl-enzyme intermediate. Nucleophilic attack by an amino group on another pilin forms a peptide bond between subunits, leading to growth of the nascent pilus. The pilus is covalently attached to the cell wall through nucleophilic attack by an amino group on a peptidoglycan precursor, probably via a separate housekeeping sortase. Reproduced from Ton-That H and Schneewind O (2004). *Trends in Microbiology* 12: 228–234, with permission from Elsevier Ltd.

localization, as it is able to attach to another subunit at only one site rather than two. Minor subunit SpaB also lacks the pilin motif, but is found intermittently along the length of the pilus. The role and mechanism of incorporation for minor subunit SpaB have not yet been defined.

Each of the three Spa pilus types in *C. diphtheriae* has its own gene cluster, encoding one major subunit, two minor subunits, and one or two sortase-like transpeptidases. *C. diphtheriae* encodes six sortase (srt) homologues in all, five of which are within predicted pilus gene clusters. *SrtA*, which is adjacent to *SpaABC*, is required for assembly of SpaA pili. The SpaD pilus gene cluster includes both *SrtB* and *SrtC*, and either of these sortases is sufficient for SpaD pilus assembly. *SrtF*, which is not linked to a pilus, is likely a 'housekeeping' sortase, responsible for anchoring a variety of LPXTG motif-containing proteins in the cell wall. *SrtF* is also required for firm attachment of SpaA pili, indicating that its cell wall-anchoring activity may be important for pilins as well as for nonpilin proteins. Because *SrtA* seems to have limited efficiency in attaching pilins to the cell wall, it has been argued that the term sortase is a misnomer, and that *SrtA* should instead be referred to as a pilin polymerase. Further research will be required to establish the exact roles of the sortase-like transpeptidases in pilus assembly and attachment.

As in Gram-negative bacteria, pili play a vital role in mediating attachment of Gram-positive bacteria to target surfaces and tissues, and thus also in pathogenesis. The dental pathogen *Actinomyces naeslundii* uses two different types of pili: one promotes colonization by adhering to saliva-coated tooth enamel and the other mediates attachment and interactions with both mammalian cells and other bacteria, potentially promoting both infection and biofilm formation. *S. pneumoniae* lacking pili show impaired adherence to lung epithelial cells, and are less virulent than their wild-type counterparts in direct competition. Recent work in clinically important group A and group B *Streptococcus* strains has shown that pili can be effective vaccine candidates for Gram-positive pathogens. Given these clinical implications, one may expect an increase in research on Gram-positive bacterial pili in the coming years.

Regulation of Pilus Biogenesis

Pilus biogenesis, in general, is a tightly regulated process. Ideally, the costs in energy and other resources required for pilus assembly must be balanced with potential benefits that pilus expression might provide a bacterium. For example, by producing pili in a nutritionally poor environment, a bacterium will tax its available resources, but with pili the same bacterium may be able to gain access to a more favorable location. Pathogenic and other bacteria must also control pilus expression, in some cases, to avoid attachment to unfavorable sites (tissues) within their hosts. Furthermore, pathogenic bacteria may need to modulate pilus expression to escape detection by the host immune system. Whether or not a bacterium expresses pili is greatly affected by environmental factors. Changes in temperature, osmolarity, pH, oxygen tension, carbon source, and nutrient availability may either increase or decrease pilus expression. The presence of iron, aliphatic amino acids, and electron acceptors other than oxygen may also influence the expression of pili. A combination of these environmental cues can stimulate (or repress) pilus synthesis and alter the expression of a number of other factors, all of which can influence the tropism of bacteria for specific niches within the environment or within host organisms.

Environmental signals affect pilus biogenesis through global regulator proteins that can modify the transcription of pilus genes. Various global regulators have been identified and include H-NS, a DNA-binding histone-like protein that often mediates temperature regulation of pilus synthesis. H-NS appears to alter DNA topology and typically functions as a negative regulator. Regulation by carbon source can occur through the catabolite activator protein (CAP), whereas the leucine-responsive regulatory protein (Lrp) can modulate pilus expression in response to aliphatic amino acids. The CAP and Lrp regulators can control sets of pilus operons, enabling the expression of different types of pili to be coordinated and integrated with the metabolic state of the bacterial cells. In addition to these and other global regulators, specific regulator proteins encoded by genes within some pilus operons may also modulate pilus biogenesis. Multiple regulatory factors can act upon the same promoter region, switching pilus gene expression from on to off and vice versa. This on and off switching, known as phase variation, can also be modulated by the methylation status of a promoter region and by the inversion of sequence elements within a promoter. Extracytoplasmic and cytoplasmic stress response pathways also appear to be involved in regulation of the assembly and function of a large number of different pilus types. In keeping with the vast array of niches filled by bacteria and the different environments to which they must adapt, regulation of pilus biogenesis is highly complex, and may vary widely among strains.

Role of Pili in Disease Processes

The expression of pili can have substantial impact on the establishment and persistence of pathogenic bacteria within both plant and animal hosts. For many bacterial pathogens, adhesive pili play a key role in the colonization of host tissues. Uropathogenic *E. coli*, for example, require type 1 to effectively colonize the bladder epithelium. These pili attach to conserved, mannose-containing host receptors expressed by the bladder epithelium and help prevent the bacteria from being washed from the body with the flow of urine. Type 1 also mediate invasion of bladder cells, and can promote bacterial survival by modulating the host immune response. For example, P pili may serve a similar function in the kidneys, preventing the clearance of pyelonephritic *E. coli* from the upper urinary tract and allowing the establishment of an infection. Enteric pathogens produce a wide variety of adhesive pili that facilitate bacterial colonization of the intestinal tract. These include the K88, K99, and 987P pili made by ETEC strains, the long polar fimbria

and plasmid-encoded fimbria of *S. enterica* ser. Typhimurium, the subclass of Afa/Dr adhesins, including F1845, Dr and Afa-3 fimbriae of *E. coli*, and aggregative adherence fimbria (AAF) of enteroaggregative *E. coli*. In the small intestine, toxin coregulated pili (TCP) are essential for the attachment of *V. cholera* to gut epithelial cells. These pili also act as receptors for the cholera toxin phage (CTXΦ), a lysogenic phage that encodes the two subunits of the cholera toxin. This phage, with its encoded toxin, is transferred between *V. cholera* strains via interactions with TCP within the small intestine. Other pili also function in the acquisition of virulence factors. The uptake of DNA facilitated by type IV pili and DNA transfer directed by conjugative pili can provide pathogens with accessory genes, enabling them to synthesize a wider repertoire of virulence factors and giving them resistance to a greater number of antibiotics. Biofilm formation, which in some cases appears to require pili such as type 1, type IV, or curli, can also increase the resistance of bacteria to antibiotic treatments and may aid bacterial colonization of tissues and medical implants.

Pili are not necessarily static organelles, and dynamic alterations of pilus structures during the infection process may influence the pathogenicity of pilated bacteria. For example, electron microscopic studies of mouse bladders infected with type 1-piliated uropathogenic *E. coli* showed that the pili mediating bacterial adherence to the bladder epithelial cells were 10–20 times shorter than typical type 1. It is possible that the shorter type 1 observed are the result of pilus retraction, compact coiling, or breakage during the infection process. The shortening of pili may provide a means for reeling bacteria in toward their target host cells, allowing the bacteria to make intimate contact with the host after initial attachment at a distance. Within the gut, type IVb pili (BFP) promote autoaggregation and microcolony formation in EPEC strains, a phenomenon that facilitates the adherence of EPEC to the intestinal epithelium. After initial attachment, an energy-dependent conformational change in the quaternary structure of BFP appears to be needed for the further dispersal of EPEC over human intestinal cells and for the full virulence of this pathogen.

During the infection process, adhesive pili are often situated at the interface between host and pathogen where they can potentially mediate cross-talk between the two organisms. Pilus attachment to the receptor of a host eukaryotic cell may induce a number of host signal transduction pathways, potentially leading to cytoskeleton rearrangements, membrane ruffling, and pathogen internalization. For example, binding of the type IVa pili of *Neisseria* to host receptors (probably CD46) on target epithelial cells has been shown to stimulate the release of intracellular Ca^{2+} stores, a signal known to control a multitude of eukaryotic cellular responses. Likewise, the attachment of P pili to Gal α (1–4)Gal-containing host receptors on target uroepithelial cells can trigger the intracellular release of ceramides, important second messenger molecules that are capable of activating a variety of protein kinases and phosphatases involved in signal transduction processes. The signals induced within uroepithelial cells on binding of P-piliated bacteria eventually result in the secretion of several immunoregulatory cytokines. Binding of type 1-piliated bacteria to mannosylated receptors on uroepithelial cells can similarly induce the release of cytokines, although apparently through different signaling pathways than those stimulated by P pilus binding. It has also been suggested that pili can transduce signals into bacterial cell, although this reported phenomenon requires further investigation and verification. Continued research into the biogenesis, structure, and function of pili not only promises to advance our basic understanding of the role of these organelles in pathogenic processes but may also aid the development of new-generation antimicrobial therapeutics and vaccines. Indeed, over the last decade, a tremendous amount of effort has been directed toward the development of pili-based vaccines and small molecule inhibitors called pilicides that can interfere with pilus assembly. At a time when the number of antibiotic-resistant bacterial strains is on the rise, effective pili-based vaccines and pilicides promise to be especially useful tools in combating bacterial infections.

Application of Pili in Immunology and Microbiology

During the recent couples of decades, the pili have been widely investigated for their application in many areas, including microbiology, immunology, vaccinology, and nanotechnology. Because of the repeated tertiary structure, pili are highly immunogenic. Because of the cell surface location, pili are used in tethering the bacteria. Here, we take the CFA/I fimbriae as an example to illustrate pili's application in the areas of immunology and immunoimmobilization.

ETEC causes both travelers' diarrhea and severe children's diseases in many endemic areas in the world. However, no licensed vaccines are available for human ETEC today. CFA/I fimbriae, a rigid fiber structure that is located on the ETEC surface, are an important virulence factor. At the primary stage of infection, ETEC needs to attach to the gut cells in the human small intestine to cause disease. The attachment of ETEC to epithelial cells is accomplished via CFA/I fimbriae. Therefore, by targeting the CFA/I fimbriae, the disease may be neutralized through the interaction between fimbrial antigen and the corresponding antibody because ETEC is an extracellular pathogen. The result in mouse model shows that two intramuscular (i.m.) immunizations with detoxed CFA/I fimbriae conferred 100% protection against intraperitoneal (i.p.) ETEC challenge, while a single dose conferred 88% protection. Challenge studies in humans also demonstrated that CFA/I fimbriae are protective antigens. Further, bactericidal assays show that ETEC is highly sensitive to anti-CFA/I sera, suggesting that parenteral immunization is critical for the effective protection. When CFA/I is expressed in a recombinant Salmonella vector, one dose of mucosal immunization can stimulate strong secretory immunoglobulin A (IgA) and serum IgG antibody responses to CFA/I fimbriae. In a word, both animal and human studies suggest that CFA/I fimbriae are a potent antigen which has the potential for generating a vaccine against ETEC. Of interest, the immune response of either purified CFA/I fimbriae or the Salmonella-carried CFA/I tends to exhibit a Th2-polarized profile. Due to the powerful mediation of the immune bias towards Th2-type immunity, CFA/I has been investigated for preventing and treating the autoimmune diseases via correcting the Th1-biased immunity to a Th2-biased immunity, such as experimental autoimmune encephalomyelitis (EAE) and collagen-induced arthritis (CIA). Studies such far demonstrated that autoimmune diseases can be successfully prevented and/or prohibited through immunizing the CFA/I in animal model.

Recently, microarrays using bacterial cells as sensors have been successfully applied in many diverse areas. After treating slide surface with anti-CFA/I antibodies in designated areas, ETEC cells are incubated on the whole slide surface. It is found that bacteria are successfully yet only tethered to the designated spots that contain the antibodies. The bacterial pattern can be easily monitored by an optical microscope. To further examine whether this technology can be extended to the diagnostic purpose, bacterial pathogens having different fimbriae are labelled with green, red, and blue fluorescence, and then they are incubated with different anti-fimbria antibodies to attach the bacteria. The results suggest that all the fimbriae, including K88ab (F4), K88ac (F4), K99 (F5), 987P (F6), F41, and CFA/I, can be used for efficient immobilization of living *E. coli*. Furthermore, when immunoimmobilization is utilized in an antibody microarray immersed in a mixed culture of pathogens, rapid and simultaneous detection of multiple pathogens can be achieved <1 h. When compared with the previous approaches using antibodies against whole bacterial cells, the anti-pili antibody to immobilize bacteria significantly enhanced the immobilization efficacy with an elevated specificity. Certainly, the specificity may be further enhanced by using monoclonal anti-pili antibody. In conclusion, both specificity and the advantage of time efficiency should allow this technology to be utilized in hospital to speed up the diagnostic procedure, particularly in regions where bacterial pathogens are epidemic.

Introduction

The Planctomycetes form a fascinating phylum of Gram-negative (from now on referred to as “diderm”) bacteria with some particular features. Taxonomically, they belong to the *Planctomycetes*, *Verrucomicrobia*, *Chlamydiae* (PVC) superphylum which also includes the *Lentisphaerae*, *Kirimateiellaeota* as well as some uncultured candidate phyla, such as the *Candidatus* Omnitrophica (previously known as OP3), the *Candidatus* Poribacteria and *Candidatus* division WWE2. The microscopic observation by Nándor Gimesi in 1924 of the characteristic rosette form of *Planctomyces bekefii* (Gr. adj. *planktos*, wandering, floating; Gr. masc. n. *mukēs*, fungus; N.L. masc. n. *Planctomyces*, floating fungus) in which spherical structures were linked to numerous filiform appendages concentrated in a common center that resembles a planctonic fungus, is responsible for the incorrect inclusion of these organisms in the fungi and for the “mycetes” designation in the name of the phylum. After the initial observation of *P. bekefii* from Lake Ligymanyosi, Budapest, Hungary, Henrici and Johnson in 1935 also found similar stalked, budding bacteria in Lake Alexander, Minnesota U.S.A., which they named *Blastocaulis sphaerica*. After these two first observations, several limnological reports evidenced the presence of similar microorganisms in freshwater lakes giving rise to the description of novel morphotypes like *P. guttaeformis* and *P. stranskae*. Thought to be unculturable, it was only in the 1970s that *Pirellula staleyi* (initially designated *Pasteuria ramosa*) was isolated in pure culture. Since then and especially in the last decades, we have witnessed an increase in the isolation of novel strains in pure culture and in the description of new taxa (Table 1). One of the organisms that is still not cultivated in pure culture is the extremely slow growing ANaerobic AMMonium OXidizing (anammox) bacteria. This “missing lithotroph”, *i.e.*, the organism capable of combining ammonium and nitrite directly into nitrogen gas anaerobically was discovered in 1999 in a wastewater treatment plant. The majority of the known Planctomycetes belong to the class *Planctomycetia* that include several orders and the “*Candidatus* Brocadiales” with still controversial positioning (Fig. 1, Table 1). In 2009 another class was described, the *Phycisphaerae* that contains the orders *Phycisphaerales* and *Tepidisphaerales* (Fig. 1, Table 1). In addition, environmental molecular studies have revealed that many non-described *Planctomycetes* exist.

Planctomycetal colonies are white, pink, orange or red pigmented. The spherical, ovoid or pear-shaped cells can display crater-like pits in the cell wall as well as different kind of hair and fimbria-like structures (Figs. 2 and 3). Planctomycetes have condensed DNA with a G+C content in the range of 50–73 mol% (the anammox Planctomycetes have G+C content around 40 mol%) (Table 1) and a 5S rRNA that is unusually short.

Members of the class *Planctomycetia* divide through polar budding (Fig. 2(B) and (C)) while all other Planctomycetes are thought to divide through binary fission. In addition, all Planctomycetes lack a recognizable homologue of the “Filamentous temperature-sensitive mutant Z” (FtsZ) protein, fundamental for cell division in all other known bacteria. Some Planctomycetes have complex life cycles in which the daughter cell is motile (Fig. 2(C)). This cell swims until it attaches to a substrate by a holdfast structure or a stalk at the vegetative pole and becomes sessile. They are slow growing bacteria with doubling times that range from 6 h up to 1 month. Their characteristic quinone is menaquinone 6. As Planctomycetes are resistant to several classes of antibiotics like betalactams, and no evidence of the presence of peptidoglycan (PG) existed, they were initially thought to be devoid of PG. Only recently the presence of genes required for PG synthesis was demonstrated in planctomycetal genomes and two independent groups demonstrated its presence in the cell wall of different planctomycetes, in a wall structure consistent with a diderm organization.

Planctomycetes have a complex cell plan due to cytoplasmic membrane invaginations that form an extensive endomembrane network (Fig. 3(C)). For some time, this complexity was interpreted as intracellular compartmentalization with the presence of an intracytoplasmic membrane that divided the cytoplasm in two compartments, one containing the highly condensed DNA and rich in ribosomes. This confusion has been recently clarified and it is now widely accepted that Planctomycetes are variations of, and not exceptions to, the diderm cell plan. The only two membranes present in all Planctomycetes, with the exception of the anammox bacteria, are the cytoplasmic (inner) membrane and the outer membrane. Both are separated by the periplasm, where PG has been observed in some and it is likely to be present in most Planctomycetes. A particular group of planctomycetes, the anammox bacteria, has an intracellular compartment which is called the anammoxosome (Fig. 3(C)). This compartment is the location of the energy metabolism of the cell - the anaerobic ammonium oxidation (anammox), an important process in the biological nitrogen cycle.

Planctomycetes share with eukaryotes the presence of clathrin-like membrane coat proteins. These proteins are encoded in their genomes and might be involved in the building of their developed endomembrane system. The encoded proteins share structural features with the eukaryotic ones involved in membrane manipulation but no sequence relationship has been shown between the two groups of proteins.

In general, Planctomycetes possess relatively large genomes, in the range of 3.9–12.3 Mb in size, but the function for only 30%–55% of the proteins encoded in these genomes can be predicted. A characteristic shared by all sequenced planctomycetal

^aAll known anammox bacteria have GC contents close to 40%.

genomes is the presence of “giant genes” (more than 5 kb) most probably encoding structural proteins, non-ribosomal peptide synthetase or polyketide synthase. Various specific molecular markers of planctomycetes have been described, which include conserved signature inserts or deletions or conserved signature proteins in ABC transporter protein, cobyrinic acid a,c-diamide synthase (protein of cobalamin biosynthesis), and Stage V sporulation protein G, SpoVG.

The ubiquity and broad phylogenetic diversity of Planctomycetes have been revealed by culture-dependent and -independent studies in the last decades. Based essentially on the analysis of the 16S rRNA gene, their presence has been detected in aquatic (marine and freshwater), terrestrial, extreme and polluted environments and in association with many organisms. This myriad of different habitats occupied by diverse planctomycetes is indicative of a great metabolic versatility that accommodates aerobic chemoheterotrophs and anaerobic chemolithoautotrophs. Many Planctomycetes are mesophilic or neutrophilic organisms. They are environmentally relevant in the global biogeochemical cycles namely carbon, nitrogen and sulfur. Planctomycetes are known for

Fig. 1 A 16S rRNA gene based tree of the phylogenetic position of selected Planctomycetes species.

their ability to metabolize *N*-acetyl-D-glucosamine as the only carbon and nitrogen source which coupled to the resistance to antibiotics are elements used for planctomycete isolation.

Biotechnologically, Planctomycetes are used for the anaerobic oxidation of ammonium in wastewater treatment plants and their potential as antimicrobial or anticancer agents has recently started to be explored. They share a complex life cycle and large genome size with Actinobacteria and Myxobacteria (both well-known producers of bioactive molecules) and possess a promising genomic repertoire of secondary metabolites.

The in-depth study of planctomycetal genomes coupled to the great effort being made to enlarge the number of sequenced Planctomycetes is providing relevant information on their unique cellular biology, structure, physiology and metabolism, evolutionary aspects and the roles played in the environment. Recently, genetic tools were developed for some Planctomycetes, which associated with the information generated by genome analyses and the increase of available new strains in pure cultures will allow a better understanding of this peculiar group of bacteria.

Particularities of Cell Structure

One of the most distinctive features of planctomycetes is their extensive and dynamic endomembrane system. Indeed, whereas most diderm bacteria have outer- and cytoplasmic membranes without major features, their organization in most members of the phylum *Planctomycetes* present modifications. Most importantly, the cytoplasmic membrane invaginates, sometimes quite extensively, towards the cytoplasm (Fig. 3(C)). This distinctive feature is more or less developed in different species of Planctomycetes. The situation in the anammox bacteria is similar to a complete enclosure, and isolation of this central region from the rest of the

Fig. 3 Transmission electron microscopy of (A) *Rhodopirellula rubra*, (B) the anammox *Candidatus Scalindua* and (C) a rosette of *Rhodopirellula lusitana*. The cells have condensed DNA, many ribosomes in the cytoplasm and fimbriae or pili on the apical pole of the cell (A and C) or surrounding the cell (B). In B is visible the anammoxosome (*). In C is visible in some cells the endomembrane network. Bar – 500 nm.

periplasm, with a possible separation from the cytoplasmic membrane, represents possibly one of the very few bacterial organelles (Fig. 3(B)) (see below). *Planctopirrus limnophila* contains one to a few major invaginations of the cytoplasmic membrane towards the inside of the cell. Eventually, the membranes of *Gemmata obscuriglobus* show a complex and extensive network of thinner invaginations of the cytoplasmic membrane. Some of these might even appear to surround the genetic material. However, a complete isolation of the DNA has been ruled out. Another type of *G. obscuriglobus* cells show an increased periplasmic volume filled with vesicles. Similar vesicles are also present in the periplasm of other Planctomycetes such as *I. pallida* and *Rhodopirellula lusitana* (Fig. 3(C)). In *G. obscuriglobus*, these vesicles have been shown to be in membrane continuity and to form a network of tubules and vesicles. The functions associated to these membrane organizations are still unknown. In *G. obscuriglobus* and in *P. limnophila*, external compounds internalization before their internal degradation has been reported associated to this membrane networks. At least in *G. obscuriglobus*, this membrane network is in close contact with proteins showing structural (but no sequence) similarity with eukaryotic proteins involved in the formation of proteic cages around bend membranes, such as the nucleopore complex or coated vesicles. In addition to the Planctomycetes, these proteins are also found in Verrucomicrobia and Bacteroidetes. The function of these proteins in bacteria is still to be defined. It is also unknown if they are homologous to the eukaryotic ones or if they have reached similar structural features by convergence.

As far as we know, the anammox bacteria are the only Planctomycetes that have a separate intracellular compartment with a specific cellular function. This anammoxosome compartment constitutes up to 60% of the cell volume (Fig. 3(B)). This compartment harbours all the (heme-containing) enzymes involved in the energy metabolism of the cell and it is hypothesized to conserve energy by the use of a proton motive force across the anammoxosome membrane. This is a highly curved, and at times extensively

invaginated, bilayer membrane. The curvature of the anammoxosome membrane might be linked to its function in energy conservation by enlarging the membrane surface area and thus the metabolic rate. Inside the anammoxosome, two structures stand out: Iron-containing electron dense particles (16–25 nm diameter) of unknown function and long tubular structures that are or contain the hydroxylamine oxidase HOX protein (kustc 1061) which is hypothesized to provide an important hydroxylamine detoxification system to the cell (see below). The anammoxosome is surrounded by the cytoplasmic compartment, which contains a condensed nucleoid that is always attached to the outside of the anammoxosome, and the periplasm. Unlike previously believed, the periplasm contains PG and most likely also an asymmetrical bilayer outer membrane typical of diderm bacteria. Finally, the outermost layer of the cell is mostly constituted by a heavily glycosylated protein surface layer (S-layer).

Anammox bacteria contain unique membrane lipids called ladderanes. They consist of (three or five) linearly concatenated cyclobutane rings bound to a polar head group by ester or ether bonds with no known preference for ester or ether binding in distinctive ladderane lipids. All membranes of the anammox cell contain ladderane lipids but they are especially abundant in the anammoxosome membrane. Their role might be in rendering the membrane less permeable and more rigid. It is hypothesized that the bacteria need a less permeable membrane to limit the passive diffusion of valuable intermediates and protons or toxic intermediates. In addition to ladderane lipids, the membranes also contain hopanoid lipids that might serve in maintaining the optimal equilibrium between membrane fluidity and rigidity.

Cell Division

Another of the fascinating features of Planctomycetes is their mode of division. Most bacteria divide by binary fission which involves lateral growth of the cell, followed by its pinching at mid-cell and division at the equatorial plane.

A similar phenomenon is observed in the orders *Phycisphaerales* and "*Candidatus Brocadiales*" which includes the anammox bacteria. Unlike most of the other Planctomycetes, anammox bacteria divide by binary fission. In the anammox, the first sign of cell division is the appearance of a putative cell division ring in an unusual location: the periplasm. Next, the cell slightly invaginates, doubles in size and finally constricts to separate the two daughter cells like in any other binary fission dividing bacteria. During the process of cell division, the anammoxosome is equally divided between the two daughter cells. However, a particularity is that anammox bacteria, like other Planctomycetes, lack some of the canonical and essential cell division genes such as FtsZ.

All other planctomycetes divide by a mode that appears more related to budding (Fig. 2(C)). Intermediary phenotypes have also been reported as in the genus *Fuerstia* where dividing cells are interconnected by a tubular like structure. It will certainly be of interest to discover novel species of planctomycetes with diverse modes of division.

Planctomycetes are however not the only bacteria that do not divide by binary fission. Where Planctomycetes are unique is that all of them are dividing without the otherwise bacterial ubiquitous protein FtsZ. Bacterial division without FtsZ remains one of the last mysteries of molecular microbiology and evolutionary cell biology. In other bacteria, FtsZ orchestrates the process of cell division, forms a ring in the cytoplasm, attached to the cytoplasmic membrane at midcell and serves as a scaffold for other cell division proteins. How cell division is organized in the FtsZ-less binary fission or budding Planctomycetes is entirely unknown and an interesting topic for future research. In addition to FtsZ, the proteomes of Planctomycetes also lack various other division-associated proteins like MurC, AmiA, RodZ or FtsA. Deciphering the modes of division of planctomycete bacteria is thus of extreme relevance not only for planctomycetal molecular biology and for microbiology but also for the field of evolutionary cell biology.

Physiology and Metabolism of Anammox

Anammox bacteria perform anaerobic ammonium oxidation in three consecutive reactions: the reduction of nitrite to nitric oxide, the condensation of nitric oxide and ammonium to the "rocket fuel" hydrazine, and the oxidation of hydrazine to dinitrogen gas (Fig. 4). The oxidation of hydrazine releases four electrons that are proposed to be transferred to a membrane-bound cytochrome bc1 complex. Cytochrome c-type proteins might serve as intermediate electron carriers, also facilitating the shuttling of electrons to the reduction of nitrite (one electron) and the synthesis of hydrazine (three electrons). The electron transport could facilitate the translocation of protons by the bc1 complex across the anammoxosome membrane, giving rise to a proton motive force. This proton motive force could then be used by membrane bound ATPases to produce ATP in the cytoplasm. Some of the electrons from hydrazine oxidation are proposed to be shuttled towards carbon dioxide reduction for carbon fixation through the Wood–Ljungdahl pathway. To replenish these electrons, some of the nitrite is oxidized to nitrate. Finally, it is proposed that anammox bacteria have a detoxification system that keeps inhibitory compounds like hydroxylamine at low concentrations. This might be done through the very abundant cytochrome c-containing protein kustc1061 which can convert hydroxylamine to nitric oxide.

For a long time, it was thought that anammox bacteria were specialists only capable of converting ammonium and nitrite into dinitrogen gas. In fact, anammox bacteria might be considered as generalists as they are also capable of converting some organic as well as other inorganic compounds. Few examples; certain anammox species can perform formate, acetate, propionate and methylamines oxidation, nitrate respiration (using iron as electron donor), and organic acid oxidation (using nitrate as electron acceptor – DNRA (dissimilatory nitrate reduction to ammonium)).

Fig. 4 Simplified model of the anammox cell plan and energy metabolism. The anaerobic ammonium oxidation takes place inside the anammoxosome compartment and proceeds in three consecutive steps: The reduction of nitrite to nitric oxide by a nitrite reductase (Nir), the condensation of nitric oxide and ammonium to hydrazine by hydrazine synthase (HZS) and the oxidation of hydrazine to dinitrogen gas by hydrazine dehydrogenase (HDH).

Anammox bacteria are slow growing; their doubling time ranges from one to several weeks depending on the growth conditions. Therefore, anammox bacteria cannot be cultivated using standard microbiological techniques such as plating. Instead, they are cultivated in bioreactor systems where they can reach an enrichment level ranging between 74% (sequencing batch reactor – floccular biomass) and 98% (membrane bioreactor – planktonic cells).

Genomes

Since 2003, year of the publication of the genome of *Rhodopirellula baltica* SH1, several planctomycete genomes have been released (Table 2) and various aspects of the biology of the Planctomycetes disclosed. The majority of the sequenced Planctomycetes have big genomes comparatively to other bacteria (over 5 Mb and up to 12 Mb) although some smaller sizes have been found in the class *Phycisphaerae*. Comparatively to the genomes of other phyla, the function for a lower number of the proteins in the genomes could be predicted, only about half or less, which represents a relevant gap in the functional understanding of Planctomycetes.

The genome of *R. baltica* revealed that this species has the conventional pathways for a heterotrophic bacteria (glycolysis, the Krebs cycle and oxidative phosphorylation) but also several other metabolic capacities like the pentose-phosphate cycle (an alternative to glycolysis), the genes for heterolactic acid fermentation and for the interconversion of C1 compounds plus an unexpected high number of sulfatases which were related to the utilization of sulfated glycopolymers produced essentially by macroalgae and thus abundant in marine environments. *R. baltica* has the capacity to synthesize all amino acids and possesses genes for nitrate transport and nitrate to nitrite reduction. The glyoxylate bypass and the Entner–Doudoroff pathway were missing. The presence of genes related to the biosynthesis of PG and of the outer membrane was already indicative of a diderm nature for planctomycetes cell wall as posteriorly demonstrated. The big size of its genome cannot be justified by multicopy genes because only 25.4% are multicopy genes in the genome of *R. baltica*, a lower value comparatively to *Bacillus subtilis* (30%) or *Escherichia coli* K-12 (29%).

Based on comparative genomics, it was observed that the Planctomycetes have the three major regulatory systems involved in transmembrane signaling typical of bacteria: one-component systems (1CSs), two-component systems (2CSs) and extracytoplasmic function sigma factors (ECFs). In general a direct correlation between the absolute numbers of signaling proteins and genome size exists. The common bacterial ratio of about four times between 1CSs and 2CSs was observed but these components differ from other bacteria in several aspects. Furthermore, planctomycetes are especially rich in extracytoplasmic function sigma factors (ECFs). ECFs control genes that regulate cell envelope related processes and are important in conferring resistance to agents that threaten the integrity of the cell envelope. Regarding planctomycetal chemotaxis, great differences were observed among eight planctomycetal genomes analyzed. While some Planctomycetes possess a high number of chemotaxis systems, others showed limited resources especially *R. baltica* that completely missed any chemotaxis machinery. Planctomycetes with a motile swarmer cell in their life cycle possess the genes for a functional flagellum but the non-motile strains only possess a restricted flagellar assembly.

Some planctomycetal genomes display an enlarged carbohydrate-active enzyme (CAZyme) repertoire as it is the case of *Paludisphaera borealis* and *Thermogutta terrifontis* that possess an extensive glycolytic potential. The evolutionary origin of the enzymes

present in *P. borealis* seems to have been acquired by horizontal gene transfer (HGT) from other phyla, such as *Proteobacteria*, *Chloroflexi*, *Cyanobacteria*, *Gemmatimonadetes*, *Verrucomicrobia* and *Acidobacteria* and not from the two phyla with great hydrolytic potential, the *Firmicutes* and *Bacteroidetes*. Planctomycetes associated to macroalgae also showed evidence for extensive HGT from the *Bacteroidetes* and *Proteobacteria*. In fact, planctomycete genomes possess genomic islands, which are horizontally transmitted gene clusters, and high number of transposable elements. Some strains also possess clustered regularly interspaced short palindromic repeats (CRISPR) that are essential in the adaptive immunity, playing a key role in the bacterial defense against invading genetic material like bacteriophages and conjugative plasmids.

The genome of several Planctomycetes have the metabolic pathways for degrading diverse toxic compounds, including ethylbenzene, aminobenzoate, naphthalene, chloroalkane, polycyclic aromatic hydrocarbon, toluene, bisphenol, benzoate, chlorocyclohexane and chlorobenzene.

Another peculiarity of planctomycete genomes is the presence of giant genes (with a size >5 kb) which could be coding for surface proteins, non-ribosomal peptide synthetases or polyketide synthases.

Recent analysis of TARA Oceans metagenomes revealed complete set of genes for nitrogen fixation in metagenome-assembled genomes (MAGs) from two Planctomycetes inhabiting the surface of the open ocean. Besides Planctomycetes, seven *Proteobacteria* MAGs also contained genes for nitrogen fixation. This is the first genomic evidence of putative of non-cyanobacterial heterotrophic bacterial diazotrophs (HBDs) in the surface of the open ocean. These HBDs were surprisingly abundant in the Pacific Ocean and the Atlantic Ocean northwest. One of the Planctomycetes MAGs with 88% identity to *Algisphaera agarilytica* represents a new order.

Ecophysiology

Planctomycetes inhabit a wide range of niches which include terrestrial, aquatic, extreme and polluted habitats. Indeed, since the discovery of members of planctomycetes in Australian soil in 1992, planctomycetes have been found widespread and abundant in different kinds of soil around the globe, such as cultivated, pasture, forest, tundra, sandy loam and thermal soils. They first have been overlooked due to a mismatch in a popular bacterium-specific 16S rRNA gene amplification primers. But their presence and quantity have been extensively detected by culture independent methods like fluorescence *in situ* hybridization, clone libraries, denaturing gradient gel electrophoresis (DGGE) and, more recently, by metagenomic approaches. Even though they appear many

times in relative low abundances, in some environments they contribute substantially to the native population as it is the case on the surface of macroalgae, in acidic *Sphagnum* peat bogs, in marine snow and in some sediments. For example, planctomycetes represent a major part of the bacterial population in mangrove wetlands, agricultural fields and lichen-dominated sub-arctic ecosystems in Siberia. They were also found in salty sandy coastal soils in China, chinese leek rhizosphere and grazed pasture soil.

Surprisingly, planctomycetes were found to be very abundant in aridic regions of China as well (23.7% of the bacterial community), while their abundance decreased along salinity gradients in comparable habitats. Another striking enrichment of planctomycetes can be observed in the active layer above permafrost soils for example on the Tibetan Plateau or in moist acidic tundra soil. This fits to the observation of planctomycetes at all stages of fennoscandian boreal forest development where they can account for up to 21% of the bacterial community. They were found to be associated with decomposing dead wood in natural temperate forests, indicating that they might be involved in the breakdown of complex carbon compounds in terrestrial habitats. Planctomycetes are also significantly enriched in the rhizosphere from an Amazon rainforest compared to the surrounding soil. Regarding taxonomy, 16S rRNA planctomycete sequences detected in soils are affiliated to various genera of the family *Planctomycetaceae*, such as *Pirellula*, *Planctomyces*, *Isosphaera* and *Gemmata* but also to non-described independent clusters.

Planctomycetes dwell in all sorts of limnic and marine habitats. For example 8.2% of the bacterial community in rivers of the upper Amazon basin are planctomycetes. Furthermore, they were detected in Hindu Kush caves, in a cold subsurface aquifer and in rain collected groundwater.

Their diversity is grouped in two clusters distantly related to *Pirellula*, *Planctomyces* and *Gemmata* but highly related to 16S rRNA gene sequences obtained from freshwater environments worldwide. This evidences the existence of globally distributed freshwater clusters of planctomycetes. In the hypereutrophic freshwater Lake Taihu, China, planctomycetes were the dominant non-cyanobacteria phylum (36% of the sequences) in the microbial community associated to carpet-like cyanobacterial blooms. In the low temperature and high altitude of two moraine lakes in Mount Everest, planctomycetes were present as 2% of water bacterial community. In two perialpine lakes with different eutrophication status, the oligotrophic Lake Annecy and the mesotrophic Lake Bourget, planctomycetes are more diversified and with less temporal variations in the hypolimnia comparatively to the epilimnia.

In lotic environments, planctomycetes were found in river snow (lotic microbial aggregates) in the river Elbe, Germany, in a relative abundance of 2% but more abundant in spring, summer and autumn and in hyporheic zone within sediments in three different streams in Montana, United States. Furthermore, in the polluted river Elbe and its tributary Spittelwasser, the biofilm community presented planctomycetes abundance peaks (7%–10%) in summer and 2% in winter that also varied in composition.

In extreme aquatic habitats like the South African salt pans with a pH of 8.0 and a salinity of 12.8%, planctomycetes form a major part of the bacterial community. A well-diversified community is present in the anaerobic, sulfide-saturated sediments of a mesophilic spring (Zodlstone Spring) in southwestern Oklahoma as assessed by the analysis of the 16S rRNA gene sequences. The diversity obtained was related to the class *Planctomycetia*, to the *Cand.* class WPS-1 and to a deeply branching clade of Planctomycetes. Many of the clones were related to the ones reported from anaerobic environments. Moreover, two novel strains related to the *Pirellula-Rhodopirellula-Blastopirellula* clade were isolated and are able to reduce elemental sulfur to sulfide under anaerobic conditions and form acids from sugars. The acidic *Sphagnum* peat bogs with a pH between 3.9 and 4.5 harbour a rich community of recently described planctomycetes with densities of 1.1×10^7 cells g⁻¹ peat. Further studies showed the presence of planctomycetes in nine different acidic or mildly acidic wetlands of Northern Russia. In some of these sites their abundance decreased sharply with depth but in two sites they present two abundance peaks in the depth profile: one in the uppermost oxic layer and another, with anoxic conditions, at a depth of 30 cm below the water table level. The upper peak was dominated by members of *Isosphaera* and *Singulishpaera* and the anoxic one with *Zavarzinella* and *Pirellula*-like representatives. In both zones, members of the *Cand.* Omnitrophica were detected. Another acidic environment also colonized by planctomycetes is the acidic El Coquito hot spring in the Colombian Andes.

Like other planctomycetes, anammox bacteria have been detected in diverse habitats including marine oxygen-minimum zones and sediments, freshwater lakes and rivers, peat soil, fish intestinal tract systems and anaerobic and oxygen-limited wastewater treatment plants. Studies in different oxygen minimum zones indicated that anammox bacteria are key players responsible for the nitrogen loss from these systems. Since oxygen minimum zones are estimated to be responsible for up to 50% of the nitrogen loss from the ocean, anammox bacteria play a major role in the nitrogen cycle on a global scale.

In addition, Planctomycetes can live in association with other organisms. In particular, microbial mats are natural enrichments of planctomycetes. For example, up to 21% of the bacterial community composition in microbial mats of the hypersaline Laguna Tebenquiche (Chile) are planctomycetes. They were identified in mats from an iron-rich thermal spring in South Africa, in mats at Little Hot Creek, USA, and in black mats in a hypersaline lake in Chile. In the latter particular habitat, even 42% of the bacterial community were planctomycetes. A special case of microbial mats are stromatolites and up to 15% of the stromatolite forming bacteria was found to be planctomycetes. Even in Antarctic marine biofilms on artificial surfaces up to 21% of the bacterial community were planctomycetes. Noteworthy, in most microbial mats and in stromatolites in particular, cyanobacteria are the most abundant bacteria. Thus, there is a striking co-occurrence of cyanobacteria and planctomycetes that was already known for cyanobacterial blooms.

Planctomycetes are particularly abundant in certain biofilms and in eukaryote-associated microbiomes. For example, planctomycetes were found to be enriched in the particle associated fraction (7%) compared to the surrounding water (1%) in samples from the Mediterranean Sea. In Wadden Sea sediments, Planctomycetes can account for up to 7% of the bacterial community on

individual sand grains, while they form on average 5.7% of the bacterial community. On marine macroscopic detrital aggregates known as marine snow 22% of the bacteria can be Planctomycetes. They are thought to degrade compounds such as sulfated polysaccharides in these particles that sink to the deep sea. Consequently, Planctomycetes can dominate deep-sea sediments, for example in the Gulf of Mexico.

Planctomycetes were described to be associated to eukaryotes. A study comparing human gut microbiota from Senegalese versus French individuals showed higher prevalence and diversity of planctomycetes (1.8% versus 0.4%, $p=0.05$) in individuals from Senegal. 16S rRNA gene sequences related to *Gemmata*, *Planctomyces*, *Isosphaera*, *Pirellula*, *Blastopirellula*, *Schlesneria*, *Singulisphaera* and *Phycisphaera* were found. Planctomycetes were identified in fecal samples of several other mammals like wild gorilla, bat and pigs. When mice were fed with a simulated fungal diet, planctomycetes were detected in the gut, while they were absent in mice on a regular diet. In other trophic levels, planctomycetes were found (1) in the gut of different species of penguins (up to 11%); (2) in the gastrointestinal track of the common carp (*Cyprinus carpio*) with a percentage of 12% where they might be involved in polysaccharide degradation; (3) in the whole gut of individuals of the damselfish and cardinalfish where an 80-fold enrichment of *Pirellulaceae* occurred between the microbiome of pre- and post-settlement larvae; (4) in the hepatopancreas (midgut gland) of the giant tiger prawn *Penaeus monodon* and in commercially important white shrimp (*Litopenaeus vannamei*) where 2.9% of the intestinal microbiota were planctomycetes and their abundance changed significantly at different culture stages; (5) as part of the coral *Montastraea cavernosa* microbiome and in association with the deep-sea octocoral *Paramuricea placomus* where even 10% of the bacterial community were planctomycetes; (6) in Baikalian fresh-water sponges; (7) in the microbiome (about 10%) of the calcifying benthic foraminifera *Amphistegina lobifera* of the Great Barrier Reef in Australia where it remains unclear whether this is or is not a symbiotic relationship; (8) in the lightless habitats of the deep-sea cold seeps dwell chitin tube forming worms (*Escarpi* sp.) and Planctomycetes form the most abundant OTU in such chitin tubes, which are extreme natural enrichments for Planctomycetes as they are barely detected in the surrounding water or sediment samples; (9) in macroinvertebrates: the hindgut of soil-feeding termites *Cubitermes* spp. and the midgut of humivorous larvae of the cetoiid beetle *Pachnoda ephippiata*. In the termites *Cubitermes* spp. planctomycetes are extremely abundant with cell densities of 2.6×10^9 cells ml^{-1} , representing one-third of the FISH bacterial counts in the alkaline hindgut. The Planctomycetes diversity forms three major clusters that are novel, deeply-branching lineages. The role played by planctomycetes in the gastrointestinal tract of the various organisms is unknown but may be related to the breakdown of products released by other bacteria like polysaccharides. The anammox planctomycetes present in the carp gut might be involved in the nitrogen cycle.

However, thus far, the best studied habitat where planctomycetes seem to play a significant role are micro- and macroalgae. Macroalgae are the dominant habitat-forming organisms on temperate rocky marine coastlines. Within mid-latitude belts, they frequently form kelp forests that provide shelter and a source of nutrition for marine mammals, fish, crabs, sea urchins, mollusks, other algae and epibiota. For example, planctomycetes could account for 51%–53% of the bacterial biofilm cells on surfaces of the kelp *Laminaria hyperborea* from Norway where they are part of a stable community over time. In addition, a broad association of planctomycetes and 12 macroalgae from the north coast of Portugal was shown through the isolation of 138 isolates in pure culture. During isolation, colonies of planctomycetes grew on the surface of portions of the macroalgae, evidencing a clear nutritional role of the macroalgae and the existence of an intimate relationship between both organisms. A novel planctomycete from the surface of the macroalga *Porphyra* sp., *Phycisphaera mikurensis* that belongs to a new class, the *Phycisphaerae* was also described. Afterwards, many other studies also confirmed the existence of this association and several new taxa were described: *Roseimaritima ulvae*, *Rubripirellula obstinata*, *Mariniblastus fucicola*, *R. lusitana*, *R. rubra*, *A. agarilytica*. Besides the new described biodiversity, macroalgae harbour representatives of *R. baltica*, *B. marina*, *Planctomyces*, the Pir4 lineage, the uncultured class OM190 and other deep branching unidentified groups. Some OTUs seem to be specifically associated with particular macroalgae. Several studies suggest that the planctomycetal-containing microbiome is host specific and probably determined by nutritional molecules provided by the algae and the set of sulfatases inherent to each planctomycete species. However, the planctomycetal association with macroalgae is not fully understood. Planctomycetes dominated the biofilms on the surface of *Laminaria hyperborean* with up to 55.7% abundance, while the biofilm composition was subject to seasonal variations. One hypothesis is that the role of planctomycetal carbon remineralization is key for the ecology of the kelp forest.

Given the slow growth of Planctomycetes -some species have doubling times of up to one month- their high abundance in such important habitats as kelp, that are packed with alluring carbon sources in contrast to the largely oligotrophic surrounding water, appears counter intuitive. Most other heterotrophs that dwell in such ecological niches divide much faster (for example 1.2–6.3 h for the *Alphaproteobacteria* *Roseobacter* sp.) and should therefore outcompete planctomycetes. Thus, the phototroph-planctomycetal allelopathic interactions might involve the production of various secondary metabolites that might act as antimicrobials (defense against other, faster growing, heterotrophic bacteria) or algicidals (to destroy algae namely diatoms or cyanobacteria for scavenging). In addition, climate change might lead to an increase in planctomycetal abundance on macroalgae: if *Caulerpa taxifolia* was incubated under higher pCO_2 , some planctomycetes were ten times more abundant than under normal pCO_2 and accounted for 5% of the bacterial community an effect that was observed in soil as well. Besides macroalgae, the planctomycetal abundance was found to correlate in two following years with a *Centrales* diatom bloom in the German North Sea and with *Skeletonema* diatoms in the Baltic Sea. In mesocosm experiments it was shown that a higher abundance of planctomycetes can correlate with environmental changes, which seems to be a more general feature in particular if pCO_2 levels are increased to simulate climate change.

However, the planctomycetal association with phototrophs is not limited to marine algae. For example, a correlation of planctomycetal abundance with chlorophyll a concentrations in a shallow mesoeutrophic lake in Italy, pointed towards a role of planctomycetes in the degradation of algal biomass. A study in the eutrophic Lake Taihu (China) demonstrated that planctomycetes

were the dominant members of the microbial community attached to *Microcystis* cyanobacteria during an intensive bloom and their abundance increased to 22% of the bacterial community during such blooms. More planctomycetal sequences were found on the surface of the freshwater macrophyte *Nuphar lutea* compared with the surrounding water, while the species composition in this natural enrichment differed from marine phototrophs such as algae. Planctomycetes were shown to be involved in phytoplankton bloom utilization in a fast-flowing, river-dominated estuary as well.

One might conclude that planctomycetes have a striking relationship with phototrophs as such while evidence point towards their main role in degradation of such phototrophs. This relationship might not be limited to aquatic habitats since for example 10.61% of the bacterial microbiome on infected citrus plants were planctomycetes as well.

Taken together, planctomycetes seem to be associated with particles, surfaces, microbial mats, biofilms and eukaryotes. However, abundance alone is no measure for environmental importance and a deeper understanding of the planctomycetal physiology is required to understand their ecological role in the environment. The current knowledge points towards a role of planctomycetes in degrading complex polysaccharides a role that fungi fulfill in terrestrial habitats. However, other than initially speculated, planctomycetes can be dominant in terrestrial habitats as well and might even be associated with fungi given the weak evidence that they might digest fungal polysaccharides in mice intestine. A field tempting to explore.

Glossary

Aster yellows phytoplasmas (AY) Phytoplasmas that belong to the 16SrI group within the '*Candidatus Phytoplasma*' genus.

Aster yellows phytoplasma strain witches' broom (AY-WB) A single phytoplasma strain belonging to '*Ca. P. asteris*' subgroup 16SrI-A that infects many plant hosts and is transmitted by the leafhopper *Macrostelus quadrilineatus* (Forbes). The strain was isolated from infected lettuce plants collected from fields in Ohio, USA. The genome of AY-WB has been fully sequenced.

Hemiptera An order of insects consisting of about 80,000 insect species that have sucking mouthparts with a rostrum capable of piercing tissues to suck out liquids. Within the order Hemiptera, three groups of phloem-feeding insects can transmit phytoplasmas from plant to plant. These groups are leafhoppers (Cicadellidae), planthoppers (Fulgoroidea), and psyllids (Psyllidae).

Mollicutes A class of bacteria with reduced genomes and no cell walls that forms one clade within the phylogeny of the Gram-positive eubacteria.

Mycoplasmas Human and animal pathogenic bacteria that belong to the order Mycoplasmatales within the class *Mollicutes*. All mycoplasmas use the UGA codon for tryptophan.

Onion yellows phytoplasma strain M (OY-M) A single phytoplasma strain of '*Ca. P. asteris*' subgroup 16SrI-B that is a pathogen of onions and is transmitted by the leafhopper *Macrostelus striifrons* and several other leafhopper species. OY-M was obtained from infected plant tissues in Japan.

Phloem Living tissue of plants that transports nutrients, including carbohydrates such as sucrose and glucose, to all parts of the plant. Phloem consists of two cell types: sieve cells and companion cells. The sieve cells form a tube in which individual cells are connected by sieve plates that have small pores. Sieve cells are live cells with various cell organelles, but don't have nuclei. They depend on companion cells for survival. Phytoplasmas are mainly located inside the cytoplasm of the live phloem sieve cells.

Phytoplasmas Insect-transmitted plant pathogens that form a monophyletic group within the class *Mollicutes*. Phytoplasmas and achleplasmas share a common ancestor and use the standard genetic code in which three codons are used as stop codons. Phytoplasmas were previously named mycoplasma-like organisms (MLOs). Recently, they were assigned to the genus '*Ca. Phytoplasma*'.

Spiroplasmas Bacteria with no cell wall with predominantly helical morphologies associated with various invertebrate hosts in pathogenic and commensal interactions. Spiroplasmas belong to the family Spiroplasmataceae of the order Entomoplasmatales within the class *Mollicutes*. Spiroplasmas use one of the three stop codons, the UGA codon, for tryptophan. Three spiroplasma species are insect-transmitted plant pathogens and share host ranges with phytoplasmas. These are citrus stubborn spiroplasma (*Spiroplasma citri*), corn stunt spiroplasma (*Spiroplasma kunkelii*), and *Spiroplasma phoeniceum*.

<i>tra5</i>	transposase
YFP	yellow fluorescent protein

Introduction

Phytoplasmas are economically important plant pathogens that are transmitted by phloem-feeding insects. These bacteria replicate intracellularly in their plant and insect hosts. Phytoplasmas have probably evolved from a Gram-positive *Clostridium*-like ancestor through genome reductions. The cells of these bacteria are small, averaging ~500 nm in diameter, and are surrounded by a single membrane and no cell wall. Phytoplasma detection has been difficult, because they are still difficult to culture and are frequently present in low numbers. Phytoplasma diagnostics have greatly improved with the accumulation of sequence information of primarily 16S ribosomal DNA genes. The complete genome sequences of five phytoplasma strains provided insights into the metabolic capabilities of phytoplasmas. Even though phytoplasma genomes are small, some of them have multiple copies of units up to approximately 20 kb in length that bear similarities to replicative composite transposons. Several efforts of scientists have focused on the functional characterization of phytoplasma virulence factors. Phytoplasmas use the Sec-dependent protein translocation system for export of virulence factors. Virulence factors characterized so far are cell surface proteins involved in insect transmission and secreted proteins of which some target plant cell nuclei and manipulate plant and insect processes.

Phytoplasmas form a monophyletic group within the class *Mollicutes*. First thought to be viruses, they are recognized as cell wall free pleomorphic bacteria (Fig. 1). They have small genomes averaging ~750 kb. Close to a 1,000 phytoplasmas have been detected in hundreds of monocot and dicot plant species all over the world. They commonly induce dramatic symptoms in plants, for example, witches' broom (clustering of branches due to the loss of plant apical dominance) and phyllody (floral organs that are changed to the condition of leaves) combined with generalized yellowing. The phytoplasmas are transmitted by sap-feeding insects

Fig. 1 Electron microscopy picture of phytoplasmas in a sieve tube of gladiolus showing virescence and phyllody in the inflorescence. Different sizes and shapes of the organisms are present (magnification X 8,000).

Fig. 3 Size comparisons of some eubacteria sizes. Phytoplasmas have the same size as mycoplasmas.

insects and crustaceans as obligate or facultative symbionts in pathogenic or beneficial interactions (Fig. 2). Unlike most other mollicutes, the spiroplasmas have helical cell morphologies in addition to the flask-like, oval, and round shapes. Three *Spiroplasma* spp. are also insect-transmitted plant pathogens. These are *Spiroplasma citri*, *S. kunkelii*, and *S. phoeniceum*. *S. citri* and *S. kunkelii* are transmitted by leafhopper species, whereas the vector of *S. phoeniceum* has not yet been identified. These *Spiroplasma* spp. can share plant and insect host ranges with phytoplasmas.

Before 1967, the disease now associated with the presence of phytoplasmas were thought to be caused by viruses. Indeed, phytoplasmas are much smaller than most other bacterial plant pathogens (Fig. 3) and they can pass through fine sterilization filters used for capturing bacteria. Furthermore, phytoplasmas are not easily cultured and are insect-transmitted. In 1967, Japanese scientists discovered by chance the presence of organisms that looked like mycoplasmas in the phloem tissues of plants that were associated with yellows and witches' broom symptoms. Since then, the name mycoplasma-like organisms (MLOs) was adopted and used to refer to the mycoplasmas found in plants. To distinguish the plant-associated mycoplasmas from the phylogenetically distinct plant infecting mycoplasmas, the trivial name phytoplasma was proposed at the Tenth Congress of the International Organization of Mycoplasma held in Bordeaux (France) in 1994.

Thanks to molecular tools, phytoplasmas were initially classified into groups based on restriction fragment length polymorphism (RFLP) patterns of polymerase chain reaction (PCR) products of 16S rDNA sequences. To date 33 groups (16SrI, II, III, etc.) have been identified. In these 16Sr groups, phytoplasmas were further divided into subgroups (16SrI-A, I-B, I-C, etc.). Later on full 16S rDNA sequences and subsequent phylogenetic analyses have provided further evidence for phytoplasma diversity. In 2004, the Phytoplasma/Spiroplasma working team within the International Research Program on Comparative Mycoplasma (IRPCM) published the '*Candidatus* Phytoplasma' species for strains with a 16S rRNA gene sequence that has lower than 97.5% similarity to that of any previously described '*Ca. Phytoplasma*' species. 43 '*Ca. Phytoplasma*' species have been described so far.

Ecology

Phytoplasmas need plants and insects for their dispersal in nature (Fig. 4). In plants, phytoplasmas are mainly located in the phloem sieve cells that transport sugars and other nutrients to plant sink tissues that need these sugars and nutrients for growth.

Fig. 4 Schematic representation of the route of phytoplasma movement between a plant and a leafhopper vector. Phytoplasmas (yellow dots) are limited to the phloem in plants. A phloem-feeding leafhopper acquires phytoplasmas from the plant phloem. Phytoplasmas that are ingested with plant sap arrive in the intestinal tract and invade (arrows) epithelial and muscle cells of the intestinal tract. Phytoplasmas enter the hemolymph (He), and from there invade (arrow) the salivary glands. They are then introduced back into the phloem tissue of host plants along with the saliva during feeding of leafhoppers.

Fig. 5 Plant of *Callistephus chinensis* (China aster) showing symptoms of virescence and phyllody associated with the presence of phytoplasmas in their sieve tubes.

Phytoplasmas spread throughout the plant by moving through the pores of the sieve plates that connect the phloem sieve tubes. Insect vectors of phytoplasmas are mainly phloem-feeding leafhoppers (Cicadellidae), planthoppers (Fulgoroidea), and psyllids (Psyllidae) of the order Hemiptera. Once acquired by their insect vectors, phytoplasmas invade their guts and salivary glands and many other tissues where they can accumulate in great numbers. They have to reach the saliva for subsequent introduction into the plant phloem during insect feeding. The latent period, that is the time between initial acquisition of the phytoplasmas by the insect vector from plants and the ability of the insect to introduce phytoplasmas back into the plants, can vary between 7 and 80 days. In plants, symptoms can develop in ~7 days after introduction of the phytoplasma by the insect vector, but it can take much longer (6–24 months), depending on phytoplasma - plant species combinations.

Phytoplasmas have a broad plant host range, which mainly depends on the plant feeding range of their insect vectors. The more than 100 members of the 16SrI ribosomal group ('*Candidatus* Phytoplasma asteris'-related strains), collectively known as aster yellows phytoplasmas (AY) (Fig. 5) are vectored by at least 30 often polyphagous insect species and, as a consequence, are capable of infecting over 300 species in 38 botanical families. A single AY strain can infect diverse plants. For example, the witches' broom

strain (AY-WB) can be transmitted by the generalist *Macrosteles quadrilineatus* (Forbes) to China aster (*Callistephus chinensis* Nees), lettuce (*Lactuca sativa* L.), *Nicotiana benthamiana* L., tomato (*Solanum lycopersicon* Mill), *Arabidopsis thaliana* L., and maize (*Zea mays* L.).

Overall, crops susceptible to AY include but are not restricted to lettuce, celery, escarole, endive, carrot, tomato, rape, cabbage, broccoli, kale, turnip, radish, onion, strawberries, flax, and potato. Susceptible ornamentals include aster, marigold, chrysanthemum, *Coreopsis*, *Primula* species, *Catharanthus*, *Delphinium*, *Gladiolus*, and *Hydrangea*. AY-susceptible woody fruit crops and ornamentals include grapevines, peach trees, blueberry, apricots and poplar trees. Wild plants and weeds that frequently border crop production fields, such as clover, plantain, purple coneflowers, *Ranunculus* spp., dandelions, parrot's feather, amaranth, false daisy, sowthistle, and Flora's paint brush, are also AY hosts. The broad range of plant hosts of phytoplasmas, along with generalist insect vectors, makes phytoplasma outbreaks unpredictable. Furthermore, because of the long incubation periods of phytoplasmas in plants and insects, outbreaks are often detected too late, that is, close to harvesting of the crops and after dispersion of the phytoplasmas by the insect vectors. This makes it harder to control or manage the disease cycle.

Economic Importance

The presence of phytoplasmas is associated with dramatic losses in many annual crop production areas. Yield losses of 60%–80% are common in leaf lettuces and carrots in years when AY phytoplasmas are prevalent. These phytoplasmas are also common in wheat, barley, and oats in some geographic areas of the world. They represent an important threat also for ornamental plants such as gladiolus and other bulbous species in which the phytoplasma presence changes the phenotype (Fig. 6). Disease symptoms induced by AY and the aphid-transmitted barley yellow dwarf virus (BYDV) are similar in small grains. A survey conducted from 2003 to 2005 in the USA states of Minnesota and North Dakota revealed that up to 49% of the production fields tested positive for AY compared to only a maximum of 5% BYDV-positive fields. Phytoplasmas are prevalent in other grain crops, such as maize. Maize bushy stunt (MBS) causes major yield losses of maize in Mexico and South America, where maize is grown throughout the year. Furthermore, in Serbia, Romania, and Bulgaria maize redness (MR) was a disease present for 60 years. Recent outbreaks of MR resulted in 40%–90% yield loss and were associated with the presence of “stolbur” phytoplasma (*‘Ca. P. solani’*) within the last 15 years. Moreover at least three different phytoplasmas were found associated with potato purple top disease that has been devastating the potato production industries of USA and Mexico. Thus, annual field crops frequently encounter outbreaks of phytoplasma diseases.

Phytoplasmas cause particularly devastating losses in high-value production crops. “Flavescence dorée” (ribosomal subgroups 16SrV-C/-D) and “bois noir” (ribosomal subgroup 16SrXII-A) phytoplasmas are a severe threat to vineyards of major grapevine growing areas in Europe affecting up to 80%–100% of the plants when in epidemic phases (Fig. 7). *Rubus* stunt (*‘Ca. P. rubi’*) phytoplasma is widespread in cultivated and wild blackberries (*Rubus* spp.); European stone fruit yellows (*‘Ca. P. prunorum’*), apple proliferation (*‘Ca. P. mali’*), and pear decline (*‘Ca. P. pyri’*), which all belong to the apple proliferation (16SrX) group, are also prevalent in fruit orchards of most European countries. In America, stone fruit trees and grapevines are infected by phytoplasmas classified in the 16SrIII group (*‘Ca. P. pruni’*). A final example is that of the phytoplasmas associated with coconut lethal yellowing disease that enclose phytoplasmas in the 16SrIV group in America and phytoplasmas of the 16SrXXII group (*‘Ca. P. palmicola’*) in western Africa (Fig. 7). These phytoplasmas have devastated coconut plantations resulting in serious losses to the national economies in countries that, in many cases, utilize coconut as a primary crop for farming, tourism, and export.

Fig. 6 Gladiolus inflorescence showing virescence (top) compared with a normal inflorescence (bottom): the presence of phytoplasmas modify the anthocyan metabolism and the flower production is therefore without commercial value and represents source of phytoplasma infection.

Fig. 7 Symptoms of grapevine yellows in leaves (left) associated with phytoplasma presence represented by reddening of the leaf lamina and therefore reduced plant production. On the right symptoms of lethal yellowing in palm represented by progressive yellowing of the external fronds that will eventually fall down leaving a bare trunk.

Phytoplasmas are also associated with diseases in ornamental and native plants and trees. Phormium yellow leaf phytoplasma, which is a '*Ca. P. australiense*'-related strain (16SrXII-B subgroup), is associated with a disease of *Phormium tenax* (New Zealand flax) that is a native plant in New Zealand and Norfolk Island. This plant has played an important role in the cultural history and (export) industry of New Zealand as its long fibers were used for a broad variety of products, including, for example, clothing. Unfortunately, in the last century, the phytoplasma disease resulted in a massive collapse of the *P. tenax* fiber industry in New Zealand. More recently, evidence was provided that phormium yellow leaf phytoplasma has spread to other plant species in New Zealand, including the native cabbage tree (*Cordyline australis*). Usually the phytoplasma infection induces yellowing and the falling of leaves, leading to the loss of the cabbage tree within 3–12 months. Similar phytoplasmas were also found in strawberries (strawberry lethal yellows) in New Zealand, and in grapevines (grapevine yellows) and papaya (papaya dieback) in Australia. In Europe and North America, trees are frequently destroyed by phytoplasmas. Elm yellows and witches' broom phytoplasmas greatly reduced elm (*Ulmus* spp.) plantations in urban and forest areas. Many of the elms surviving to severe epidemic of Dutch elm disease actually died for phytoplasma infections. Ash yellows phytoplasma ('*Ca. P. fraxini*') induces slow growth, progressive dieback of stems, leaf necrosis, yellowing, and witches' broom symptoms in ash trees (*Fraxinus* spp.). In several cases, 30% mortality rates of ash trees due to phytoplasma infections have been reported mainly in USA.

There is a general concern that phytoplasma disease incidences will increase in the future. An increase in phytoplasma epidemics is expected in more intensive farming in which crops may be grown the whole year round. For example, outbreaks of corn stunting agents, including MBS phytoplasma, corn stunt Spiroplasma (CSS, *S. kunkelii*), and Maize rayado fino virus (MRFV), are prevalent in regions of Brazil, Argentina, and Mexico where maize is grown in summers and winters. This is because the leafhopper *Dalbulus maidis* (Cicadellidae), which uses maize as the main feeding and developmental host and is the most important vector of MBS, CSS, and MRFV in these regions, can reproduce all year round, resulting in massive population sizes of this leafhopper. In contrast, in regions where maize is grown once a year, only few *D. maidis* survive and, consequently, incidences of these infections are less frequent.

Global warming is likely to result in greater phytoplasma outbreaks in the temperate regions of the world. Leafhoppers generally do not survive for long periods in areas with below-freezing temperatures, but several species can migrate for long distances. For example, the leafhopper *M. quadrilineatus* (Cicadellidae) does not survive the snow and below-freezing temperatures of northern America, but in spring it migrates north from southern regions where temperatures generally remain above 0 °C in winter.

M. quadrilineatus is the vector of many AY phytoplasmas. Temperate regions in Europe and northern America that have experienced warmer winters in the past years have simultaneously experienced more problems with leafhopper-transmitted phytoplasmas in various crops such as ornamental flowers, and trees. It should be noted that insect vector populations may also have increased because of a decrease in pesticide use in recent years.

The presence of phytoplasmas in diseased and asymptomatic plants is probably underreported to a great extent. The major reason is that phytoplasma detection is not easy. Phytoplasmas were only cultured *in vitro* recently and some technical problems with these approaches persist, they also are often present in low numbers, especially in plants that are in a dormant stage of their life cycle. Enzyme-linked immunosorbent assay (ELISA)-based techniques are not sufficiently specific in most cases. However phytoplasma diagnostics have greatly improved since the 1990s. Molecular techniques and phytoplasma genome sequences became available allowing the development of sensitive and specific PCR techniques. PCR combined with RFLP analyses and sequencing enabled phytoplasma identification in the preliminary 'Candidatus' taxon or at the ribosomal group and subgroup level. Through these methodologies, the huge diversity of phytoplasmas, their ability to infect a broad range of plant species and the presence of two or more phytoplasmas in one diseased plant species were discovered. It also became apparent that plant species can harbor phytoplasmas but are asymptomatic. Quantitative PCR (qPCR) and bioimaging techniques to quantify phytoplasma concentration in plants and insects have been developed. These techniques are important to obtain a more fundamental understanding of phytoplasma growth curves in plants and insects, which in turn, will help to determine differential susceptibility of plant species and varieties to the phytoplasma infections.

Association With Plants

In plant hosts, the mature sieve tubes of the phloem normally contain the highest concentration of phytoplasmas (Fig. 1). In addition, intracellular phytoplasmas with various morphologies, some probably caused by budding or multiplying, were also found inside the cytoplasm of immature phloem element. Furthermore, phytoplasmas have been detected in the cytoplasm of phloem parenchyma cells adjacent to sieve elements, inside parenchyma cells in or close to the vascular system of *Cascuta* shoots, and in embryos of coconut. Phytoplasmas were detected in seed and in seedlings from infected mother plants of a number of species such as maize, tomato, alfalfa, sesame, winter oilseed rape, and there is also some evidence that phytoplasmas can be transmitted to not only next-generation plants but also, only in the case of some tomato variety, to second generation plants. These phytoplasma plants are usually asymptomatic.

AY-WB is usually abundant in phloem tissue of sink areas, such as young shoots and roots, consistent with the development of typical symptoms (witches' broom) in these young tissues. Some phytoplasmas (e.g., MBS) induce severe phloem necrosis in their host plants, indicating that these plants react to the phytoplasma infection. However, many phytoplasmas, including AY-WB, do not induce phloem necrosis but accumulate in high numbers in phloem elements. As has been shown for several other bacterial plant pathogens, it is likely that phytoplasmas produce a series of virulence proteins that suppress plant responses.

Phytoplasmas generally have a negative impact on the fitness of their plant hosts. Plants are frequently stunted and may not produce normal flowers, fruits, or seeds. In contrast, phytoplasmas may have a positive effect on their insect vectors. For example, the longevity and number of offspring of the aster leafhoppers (*M. quadrilineatus*) can significantly increase when AY-infected, as compared to healthy China aster, lettuce, carrots (*Daucus carota* L.), and periwinkle [*Catharanthus roseus* (G) Don]. In addition, some leafhopper species of the genus *Dalbulus* that carry MBS phytoplasmas live longer when deprived of their main plant-feeding host compared to leafhoppers that do not carry them. Phytoplasmas can also manipulate plants to become new hosts for leafhoppers that normally do not use these plants as hosts. For example, the leafhopper *D. maidis*, which is a maize specialist, can feed and survive on AY-infected but not on healthy lettuce and China aster plants. In fact, the survival rates of *D. maidis* on AY-infected China aster plants and healthy maize plants are comparable. Similar findings were reported for nine leafhopper species on AY-infected celery (*Apium graveolens* L.) and China aster. Thus, phytoplasmas have a remarkable effect on the interactions between insects and plants, that is, they may convert plants from being nonhosts into hosts or better hosts for some phloem-feeding insects.

The mechanism by which phytoplasmas convert plants into more attractive hosts for insects is not yet known. One explanation for this conversion is that phytoplasma infection induces the production of additional younger green/yellow plant tissues (witches' broom, phyllody, virescence, and yellowing) that is more attractive to leafhoppers, which prefer young green/yellow tissues for feeding as well as for egg laying. It is also possible that phytoplasmas are involved in the down regulation of insect-specific defense responses in plants to attract maladapted insects and improve insect fitness on these plants. For example, phytoplasmas may be able to down regulate general defense responses to insects, such as the jasmonic acid signaling pathway that is involved in defense responses to leafhoppers.

Varieties of some plant species have some degree of resistance or are to some extent tolerant of the phytoplasma presence. However, phytoplasma resistance genes have not yet been cloned and characterized. Unlike the majority of bacterial plant pathogens that are extracellular and use specialized secretion systems for delivering virulence factors into plant cells, phytoplasmas are phloem-limited intracellular pathogens of plants and release their virulence factors directly into the plant cell cytoplasm. Hence, plant resistance mechanisms to phytoplasmas will most likely differ from those of other bacterial pathogens.

Association With Insects

When acquired by the insect vectors from plants (Fig. 4), phytoplasmas have to attach themselves to the membranes of midgut epithelial cells, on or between microvilli, and initiate the midgut colonization. Spiroplasmas and mycoplasmas have specific tip structures that are primarily responsible for attachment to cell membranes between microvilli. Such tip structures have not been identified in phytoplasmas, but it is likely that phytoplasmas use a comparable mechanism for attachment. At least one membrane protein, the antigenic membrane protein (AMP), important for insect invasion of onion yellows phytoplasmas strain M (OY-M), has been identified.

Phytoplasmas can accumulate in large numbers outside the basal lamina of these epithelial cells in the hemolymph, hemocytes, and particularly in muscle fibers and tracheae that form the outer layer of the midgut. Phytoplasmas, *S. citri* and *S. kunkelii* accumulate at similar locations in their leafhopper vectors. There is evidence that *S. kunkelii* ruptures the extracellular matrix of the basal lamina of the midgut, possibly with specific enzymes, for entering the hemolymph. The hemolymph provides a vehicle for these mollicutes to reach other tissues, including the salivary glands.

Insect salivary glands can get heavily infected with AY-WB and MBS. Individual phytoplasma cells appear to reside directly, and probably multiply, in the cytoplasm of salivary gland cells sometimes close to the nucleus. Like spiroplasmas, phytoplasmas probably enter the canaliculi at the center of secretory cells, before reaching the main salivary duct that leads to the stylet's salivary canal. They are then introduced into the plant phloem elements along with the insect salivary secretions during feeding (Fig. 4).

Metabolism

All members of the class *Mollicutes* are resulting from severe genome reductions. The genome of the mollicute *Mycoplasma genitalium* was the first to be sequenced to completion because it has one of the smallest genomes (580 kb) for a living organism. *M. genitalium* and many other mycoplasmas lack many anabolic pathways, including those for synthesis of amino acid, purines and pyrimidines, and fatty acids. In addition, even though the glycolytic pathway for catabolic metabolism is present, mycoplasmas generally lack tricarboxylic acid cycle and electron transport systems. Spiroplasmas have maintained more metabolic genes. For example, they still have the majority of the amino acid synthesis pathways, and more cytoskeleton genes that play a role in the formation of helical cell shapes typical to most spiroplasmas. Spiroplasmas have genome size ranging from 760 to 2,220 kb. Mycoplasmas and spiroplasmas also have phosphotransferase transport systems (PTSs) for import of glucose, trehalose, and fructose to feed the glycolytic pathway.

The complete genome sequences of two phytoplasmas (OY-M and AY-WB) revealed that phytoplasma genomes are even more reduced than those of mycoplasmas and spiroplasmas. AY-WB and OY-M lack PTSs for the import of sugars essential for glycolysis. AY-WB and OY-M also lack F-type ATP synthases. This is in contrast to mycoplasmas and ureaplasmas that have these ATP synthase complexes, including the A, B, and C subunits for the transmembrane channel and the five-subunit (alpha, beta, gamma, delta, and epsilon) catalytic core for ATP synthesis. Phytoplasmas have a rudimentary set of genes involved in SOS response and the standard recombination pathway, including only, *recU*, *ssb*, *polA*, *gyrA*, and *gyrB*.

The phytoplasma metabolism appears different from that of mycoplasmas and spiroplasmas in several ways. Even though phytoplasmas do not have PTS systems to feed the glycolysis pathway, they seem to possess ABC transporters for the import of maltose, including a maltose-binding protein (MalE) that may have affinity to maltose, trehalose, sucrose, and palatinose. Affinity of MalE to trehalose is likely, as trehalose is a major sugar in the insect hemolymph. However, the fate of these sugars after import is not clear, because enzymes required for the conversion of these sugars to glucose-6-phosphate for glycolysis were not found in the phytoplasma genomes. Furthermore, the sucrose phosphorylase gene, which is important for sucrose degradation, is fragmented in the OY-M phytoplasma genome and is completely absent from the AY-WB phytoplasma genome.

Phytoplasmas and mycoplasmas apparently use different routes for the generation of pyruvate. Phytoplasmas have malate/citrate-sodium symporter genes for import of L-malate or related molecules such as oxaloacetate, and a NAD-specific malic enzyme (EC 1.1.1.38) for generating pyruvate. In contrast, mycoplasmas and spiroplasmas predominantly use L-lactate dehydrogenase (EC 1.1.1.27) for converting L-lactate into pyruvate. Thus, phytoplasmas may use malate/oxaloacetate as carbon sources.

Unlike mycoplasmas, phytoplasmas appear to be capable of biosynthesis of at least some of their own membrane phospholipids. The genomes of AY-WB, OY-M, and Western X-disease phytoplasma contain the *pssA* and *psd* genes encoding CDP-diacylglycerol-serine-O-phosphatidyltransferase (EC 2.7.8.8) and phosphatidylserine decarboxylase (EC 4.1.1.65), respectively. Both are part of the phosphatidylethanolamine pathway. Furthermore, the AY-WB and OY-M genomes contain a candidate *pmt* gene for phospholipid N-methyltransferase that is involved in phosphatidylcholine synthesis in conjunction with PssA and Psd. Phosphatidylcholine is a phospholipid that is a major constituent of cell membranes. AY-WB and OY-M also have all enzymes that link the glycolysis pathway to the glycerolipid pathway and an ABC transporter gene, *phnL*, involved in lipoprotein release.

Repeat-Rich Genomes

Even though phytoplasma genomes are small, they contain many repeated sequences. The AY-WB and OY-M genomes both contain long repeating units of DNA. Of the 671 predicted open reading frames (ORFs) on the AY-WB chromosome, 191 (28%) ORFs covering 97,374 bp (13.8%) are present as multiple copies. Of these 191 ORFs, 134 ORFs (20%) are contained in clusters named

potential mobile units (PMUs) or sequence variable mosaic (SMV). The studied PMUs consist of ORFs in a conserved order that all point in the same direction on the AY-WB chromosome. The ORFs that have similarities to sequences of other organisms are sigma factor (*sigF*), single-stranded DNA-binding protein (*ssb*), DNA-binding protein HU (*himA*), Zn-dependent protease (*hflB*), thymidylate kinase (*tmk*), DNA helicase (*dnaB*), DNA primase (*dnaG*), and transposase (*tra5*). One or more ORFs with unknown functions, of which some are predicted to encode membrane-targeted proteins, are present in three locations on PMUs, that is, between *himA* and *hflB*, *hflB* and *tmk*, and *dnaG* and *tra5*. The AY-WB genome contains three apparent full-length PMUs (PMU1, 2, and 3) and many PMU-like sequences that appear to be degenerated versions of PMUs based on the presence of partial ORFs and deletion of PMU sections. The repeated presence of PMUs, their gene contents, including genes for recombination (*tra5*, *ssb*, *himA*) and replication (*dnaG*, *dnaB*), and their conserved gene orders suggest that the PMUs are replicative composite transposons. Clusters that contain one or more PMU ORFs were also found in other phytoplasma genomes in addition to the AY-WB and OY-M phytoplasmas, and were named sequence-variable mosaics (SVMs).

The *tra5* gene encodes a full-length ORFAB fusion transposase of the IS3 family insertion sequences. In most bacteria, the IS3 ORFs A and B are two separate ORFs in which the protein product of ORFA suppresses transposition activity, and the ORFAB fusion, which encodes the active transposase, is produced only in the event of a frameshift. The separation of ORFs A and B is important to prevent too frequent transposition events and subsequent genome alterations. In contrast, the majority of PMU *tra5* genes of AY-WB encode full-length ORFAB-fused transposases, suggesting that these transposons are continuously active. However, most *tra5* ORFs are preceded by a conserved sequence of 395 bp, indicating that *tra5* expression is regulated. This conserved 395 bp region coincides with the presence of conserved ~330 bp repeats that flank PMU1, and are present in PMU3 and other PMU-like regions. The function of these ~330 bp repeats is unclear. One possibility is that they mediate assembly of both ends of PMUs to enable transposition or PMU replication in the presence of the transposase.

PMUs apparently have had a major role in the phytoplasma genome evolution. The AY-WB genome is approximately 150 kb smaller than the OY-M genome, primarily due to fewer PMU sequences. In addition, alignment of the AY-WB and OY-M genomes revealed that regions containing PMUs in both genomes had undergone various rearrangements, whereas regions without PMUs had not. Indeed, generally large repeated DNAs have a destabilizing effect on a bacterial genome since they can recombine to generate deletions, inversions, and duplications of genome segments. The PMUs themselves apparently undergo rapid degeneration as evidenced by the presence of PMU-like regions carrying truncated copies of PMU genes and lacking various segments of full-length PMUs. There are also large differences in genome sizes and compositions in other members of '*Ca. P. asteris*', ranging from 660 to 1,130 kb and consisting of several fragments of 500 kb and larger. It is possible that PMUs are capable of splitting a single chromosome into two smaller chromosomes. The phytoplasmas sequenced so far have an incomplete set of genes involved in DNA recombination, including the lack of a full-length *recA*. The absence of these genes is likely to increase the stability of repeat-rich genomes.

Virulence

Several phytoplasma potential virulence factors have been characterized in recent years. It is likely that membrane proteins located on the exterior of the phytoplasma cell and secreted phytoplasma proteins play important roles in the interactions of phytoplasmas with plant and insect host cells. Indeed, one surface-exposed membrane protein, named Amp, appears to be involved in determining the transmissibility of OY phytoplasma by specific insect vectors. This protein interacts with insect microfilament complexes of the leafhopper intestinal tracts *in vitro* and *in vivo*. However, the OY Amp binds to microfilament complexes of only those leafhopper vectors that can transmit OY and not of leafhoppers that cannot transmit OY. Thus, Amp appears to determine insect specificity by mediating interactions of phytoplasmas with the first barrier to leafhopper infection, the insect gut.

The Amp of OY and other phytoplasmas constitute one type of a subset of proteins that are named immunodominant membrane proteins (IDPs). The IDPs make up a major portion of the exterior cell surface of most phytoplasmas. IDPs of many phytoplasmas have been characterized and have been classified into three major types. These are Amp, IDP, and immunodominant membrane protein A (IDPA). These three protein types are not orthologous to each other, but may have roles comparable to that of OY Amp in determining interactions with the insect host. This is consistent with the observation that IDPs are apparently undergoing positive selection. The sequence similarities among members of each type of different phytoplasmas are usually lower than sequences located adjacent to the genes encoding IDPs. Also, the portions of the IDPs that are exposed toward the surfaces of phytoplasmas that are likely to be in direct contact with host components are more divergent compared to portions of IDPs that are inside the phytoplasma membranes that are generally not in direct contact with host components. Thus, the surface-exposed portions of the IDPs seem to have accumulated changes in sequence in order to adapt to the host environment (i.e., positive selection).

Surface-exposed proteins of spiroplasmas are also involved in insect transmission. Phytoplasmas and spiroplasmas follow a similar route through their insect vectors, that is, they have to invade and escape the gut and salivary glands. Spiralin is a 26 kDa lipoprotein that is the most abundant protein on the cell surfaces of spiroplasmas, and it binds insect glycoproteins. A *S. citri* mutant with a disrupted spiralin gene multiplies at high titers in leafhopper vectors and plants, but the leafhopper transmission of this mutant is 100 times less efficient than of wild-type *S. citri*.

Phytoplasmas appear to predominantly secrete proteins via the Sec-dependent translocation system. So far, researchers have focused on the characterization of virulence (effector) proteins of Gram-negative bacteria. These bacteria generally remain

extracellular and use specialized secretion systems, such as the type 3 and type 4 secretion systems, for injecting effector proteins into host cells. The effector proteins introduced via these specialized secretion systems are involved in the suppression of plant defense mechanisms that plants trigger upon recognition of microbe /pathogen-associated molecular patterns (MAMPs/PAMPs) and avirulence proteins of the Gram-negative bacteria. Compared to Gram-negative bacteria, phytoplasmas have a quite different biology. First, they are located mainly intracellularly and can deliver proteins directly into the cell cytoplasm through the Sec-dependent pathway without the need of “injection needles” generated by type 3 and type 4 secretion systems. Furthermore, because phytoplasmas are more related to Gram-positive bacteria and lack an outer cell wall, they do not carry many of the MAMPs/PAMPs known to trigger the defense mechanisms to Gram-negative bacteria in plants.

Phytoplasmas have a functional Sec-dependent protein secretion system. The three genes for SecA, SecY, and SecE required for successful translocation of proteins across the membrane are present in the OY-M and AY-WB genomes. Furthermore, the immunodominant protein Amp is a substrate for the phytoplasma Sec system. Amp has an N-terminal signal peptide (SP) sequence that is recognized by the Sec system and is cleaved upon secretion, as in other bacteria. The SPs of mollicute proteins carry obvious similarities in composition compared to those of other bacteria. Thus, computer algorithms that can predict the presence of SPs at the N-termini of proteins, such as SP and pSORT, are useful for the mining of phytoplasma genomes for other secreted proteins. Indeed, among the 695 proteins identified in the AY-WB genome, 76 proteins contain SPs. Of these 76, 20 proteins contained a SP and additional transmembrane domains as predicted by TMHMM2.0. Protein AY-WB_599 that has similarity to OY Amp was in the list of 20 proteins. The remaining 56 proteins contained only SPs and no additional transmembrane domains, and are therefore likely secreted into the extracellular environment of AY-WB. This list of 56 proteins contains the five solute-binding proteins (SBPs) ArtI (AYWB_263), DdpA (AYWB_529), NlpA (AYWB_588), ZnuA (AYWB_624), and MalE (AYWB_667). The presence of AY-WB Amp and SBPs in the list of 76 proteins validates the SP predictions by the computer algorithms.

SBPs are frequently involved in bacterial virulence. For example, the SBP Sc76 of another insect-transmitted mollicute pathogen, *S. citri*, is important for infection of the salivary glands and transmission by the leafhopper *Circulifer haematocaps* (Cicadellidae). Many SBPs, including Sc76, are lipoproteins that remain attached to the bacterial membrane through a lipid anchor at the first conserved cysteine residue of the mature peptide. None of the five AY-WB SBPs and 51 other predicted secreted proteins have a conserved cysteine residue at the +1 position. Hence, the 56 secreted AY-WB proteins (SAPs) are likely released in the extracellular environment of AY-WB upon secretion, and therefore are putative effector proteins involved in the manipulation of plant and insect cells.

Additional independent evidence that the AY-WB SAPs are effector proteins was obtained. Two phytoplasma effectors, SAP11 and SAP30, contain eukaryotic nuclear localization signals (NLSs) that are functional in plant cells. Yellow fluorescent protein (YFP) fusions of SAP11 and SAP30 accumulated in nuclei of *N. benthamiana* cells, whereas YFP fusions of SAP11 mutants in which various portions of the NLS domain were deleted distributed throughout the plant cells. In *N. benthamiana*, nuclear localization of YFP-SAP11 requires a host factor, importin α , that is required for import of proteins into plant nuclei, including virulence proteins of plant pathogens. In immunofluorescence microscopy experiments with a specific antibody to SAP11, it was shown that SAP11 also accumulates in nuclei of AY-WB-infected China aster cells. Thus, SAP11 and perhaps also SAP30 are likely virulence factors involved in the manipulation of plant processes.

The unstable genomes of phytoplasma allow for relatively quick selection of spontaneous mutants. OY-M and NIM (OY-NIM) that were maintained in plants by insect transmission and grafting, respectively, gave rise to the non-insect-transmissible line OY-NIM. Comparison of the plasmids of OY-M and OY-NIM revealed that OY-NIM plasmid lacks two ORFs that are present on the OY-M plasmid. Thus, plasmids are also involved in insect transmission of phytoplasmas.

Conclusions

Phytoplasmas are economically important plant pathogens that affect annual and perennial crops, bushes and fruit trees, ornamental trees, and natural floras worldwide. All phytoplasmas are transmitted by phloem-feeding insects, mostly leafhoppers, planthoppers, and psyllids. Phytoplasmas have a unique biology among bacteria, because they need plants and insects for survival in nature and they can effectively multiply in both hosts. Furthermore, they replicate intracellularly in plants and insects. Phytoplasmas have evolved, along with other mollicutes, from a Gram-positive *Clostridium*-like ancestor through genome reductions and loss of outer cell wall. The cells of these bacteria are small but pleomorphic, averaging ~500 nm in diameter, and are surrounded only by a membrane.

Phytoplasma detection has been difficult they are frequently present in low amounts, particularly in dormant plants. Phytoplasma diagnostics have greatly improved with the availability of PCR methods and the accumulation of phytoplasma sequence information. The recent achievement on phytoplasma isolation from infected plants looks promising for further improvement of knowledge and diagnostic tools that will allow a focused management of phytoplasma associated diseases. Phytoplasma classification, now consisting in 43 ‘*Candidatus*’ species and 33 ribosomal groups, as well as huge number of subgroups, will also benefit future progress.

Phytoplasmas have small genomes lacking major known metabolic pathways. The complete genome sequences of two phytoplasmas provided some insights into the anabolic and catabolic pathways utilized by phytoplasmas. Recently three other phytoplasmas were fully sequenced a ‘*Ca. P. mali*’ strain, representing one of the few prokaryotes with a linear chromosome, and two strains of ‘*Ca. P. australiense*’ that share several features with those already studied. These sequences revealed that the metabolic

requirements of phytoplasma seems to be different from the related mycoplasmas and spiroplasmas, albeit some phytoplasmas and spiroplasmas share the same plant and insect hosts. Even though phytoplasma genomes are small, they are repeat-rich. The repeats are clustered into large units, named PMUs and SVMs, which have had a major influence on phytoplasma genome evolution. These repeats are likely responsible for the large differences in sizes and compositions among phytoplasma genomes. The gene content and repeated presence of PMUs in the phytoplasma genomes suggest that they are replicative composite transposons.

More recent efforts of scientists have focused on the characterization of phytoplasma virulence factors. Proteins expressed by plasmids and abundant cell surface proteins are virulence factors involved in insect transmission. Phytoplasmas use the Sec-dependent protein translocation system for secretion of virulence factors, including effector proteins, into plant and insect hosts. Several effector proteins of the AY-WB phytoplasma target nuclei of plant cells and are likely involved in the manipulation of plant processes. Extending the concept of effectors to the phytoplasmas points to novel research strategies for unraveling pathogenicity mechanisms of these fascinating pathogens.

Preliminary evidence that phytoplasmas can be grown in cell free media in a suitable and flexible medium has been reported. This is an important development to facilitate the study of the phytoplasma biology. Further studies in progress aim to validate this result and to confirm that, despite the reduced genome size and the tight relationship with their hosts, phytoplasmas seem to retain an independent metabolism.

Plastics: Colonization and Degradation

Plastics, a Diversity of Synthetic Polymers

Plastic is defined as “material that contains, as an essential ingredient, one or more organic polymeric substances of large molecular weight, is solid in its finished state, and, at some stage in its manufacture or processing into finished articles, can be shaped by flow” (ASTM standard D883). While all plastics are polymers - meaning that they are repeated units of monomers - many polymers are not plastic (e.g., cellulose, starch etc.). Likewise, plastic can be synthesized from both petrochemical (fossil fuel-based) or biological (corn, soybean) stock sources, the later earning the label “bio-based”. An example of this is polyethylene produced from corn made into drink bottles. These terms sometimes cause confusion in the literature because the term “bio-based” refers to the raw materials used to manufacture the plastic, and is not synonymous with “biodegradable”, referring to “end of life” characteristics.

While plastic is sometimes considered a monolithic entity, one need only refer to resin identification codes on commonly discarded plastic consumer items to note the diversity of polymers in use. There are in fact hundreds of plastics commercially produced with the most common being polyethylene (high density HDPE - resin code 2; low density LDPE - 4); polypropylene (PP - 5); polyethylene terephthalate (PET - 1); polyvinyl chloride (PVC - 3); and polystyrene (PS - 6). Code 7 refers to “other” plastics and includes acrylic, nylon, polycarbonate (PC) and polylactic acid (PLA) (Table 1). Nearly all plastics contain additives such as plasticizers or colorants and other organic and inorganic compounds that impart the desired final characteristics in the polymer. The ability of plastics to be reshaped categorizes them further into thermoplastics and thermosets. Thermoplastics include HDPE, LDPE, PP, PET, PS and PVC that can be reheated and reformed while thermosets (e.g., polyurethane, epoxy, silicone and melamine to name a few) undergo chemical modifications when heated that prevent reheating and re-molding. Although the first “plastics” were invented in the early 20th century (bakelite, a phenol formaldehyde thermoset), it wasn’t until the end of World War II that mass production of plastics began. According to PlasticsEurope, in 2016 the world production of plastics (excluding PET fibers, PA fibers, PP fibers and polyacryls-fibers) was 335 million metric tons, an increase of 13 million metric tons from 2015. Asia leads production in plastics materials at 50% of the total, with Europe at 19% and NAFTA countries (USA, Canada, and Mexico) at 18%.

Plastics have recently received much attention in the scientific and popular press due to a growing awareness of plastic litter in the ocean concentrated in so-called “Garbage Patches” or open ocean accumulation zones. Once thought to be restricted to the five ocean gyres - concentrations of plastic are also being described in the Polar regions and the Mediterranean. Most of the plastic that accumulates in accumulation zones is confetti-sized (<5 mm) and small pieces dominate visible plastic marine debris (PMD) numerically, but macroplastic (>5 mm) still accounts for the largest volume of plastic debris floating in our oceans. An estimated 8 million tons of plastic garbage enters the ocean each year, but estimates of total global floating plastic based on existing data are all

Table 1 Common petroleum and bio-based plastics and their behavior in aquatic environments

<i>Plastic</i>	<i>Abbr.</i>	<i>Resin ID code</i>	<i>Production</i>	<i>Origin(s)</i>	<i>Behavior in aquatic environment</i>
Polyethylene terephthalate	PET	1	Synthetic	Petroleum or bio-based	Sinks
High-density polyethylene	HDPE	2	Synthetic	Petroleum or bio-based	Floats

Poly-3-hydroxybutyrate	PHB	7	Biological	Bio-based	Sinks
Poly-hydroxyvalerate	PHV	7	Biological	Bio-based	Sinks
Poly-hydrohexanoate	PHH	7	Biological	Bio-based	Sinks
Other biodegradable aliphatic polyesters					
Polyglycolic acid	PGA	7	Synthetic	Petroleum or bio-based	Sinks
Polylactic acid	PLA	7	Synthetic	Petroleum or bio-based	Sinks
Polybutylene succinate	PBS	7	Synthetic	Petroleum	Sinks
Polybutylene succinate adipate	PBSA	7	Synthetic	Petroleum	Sinks
Polycaprolactone	PCL	7	Synthetic	Petroleum	Sinks
Biodegradable polybutylene terephthalate (PBT) aromatic polyester derivatives					
Polybutylene succinate terephthalate	PBST	7	Synthetic	Petroleum	Sinks
Polybutylene adipate terephthalate	PBAT	7	Synthetic	Petroleum	Sinks
Polytetramethylene adipate terephthalate	PTMAT	7	Synthetic	Petroleum	Sinks

far lower than this annual input, so an important question is where is the missing plastic? Many plastics are less dense than water and float, though others, including most bio-based plastics are more dense than water and sink (Table 1). Because it is inexpensive and versatile, plastic use continues to increase, and its durability allows it to persist in the environment, presenting a threat to wildlife and polluting marine ecosystems. Mostly as a result of public pressure, there are new laws coming into effect that will ban the use of plastic microbeads in some consumer products and plastic bag bans are becoming more widespread world-wide. China will no longer accept foreign plastic waste for recycling; so many nations must rethink how to handle their plastic waste infrastructure.

Living in the Plasticsphere: Colonization

The problem of PMD in the ocean gained media attention due to entanglement of and ingestion by large charismatic megafauna such as marine mammals, sea turtles, and birds, as well as reports on the accumulation zone in the North Pacific, what was called the “Great Pacific Garbage Patch”. In the last five years, however, examination of the impact of plastic pollution on the entire marine ecosystem has increased dramatically. This includes examining the impacts and consequences of plastic litter at a scale relevant to microbial life - in the realm of microplastics that are defined as pieces of plastic that are <5 mm in size. Microplastics, whether primary particles that constitute pre-production pellets and microbeads employed in cosmetics or industry, or secondary fragmented remnants of larger items, has earned center stage in the environmental science arena. The estimated trillions of microplastic pieces in the ocean represents a new, anthropogenic substrate, and the thin layer of life that forms on the surface of this plastic - often referred to as the Plasticsphere - is rapidly becoming an active focus of environmental microbiology research (Fig. 1). The Plasticsphere is home to all three domains of microbial life, as well as many multicellular organisms. The discovery of the Plasticsphere in the ocean has prompted scientists working in freshwater environments to carry out parallel investigations, confirming the ubiquity of microbial assemblages associated with plastic in all aquatic environments.

Colonization of surfaces in natural and anthropogenic environments (i.e., biofouling) has been a topic of investigation for decades and the field even has a dedicated journal. Much of this research is aimed at trying to figure out how to prevent surfaces from serving as a habitat for microbial and macrobial life on structures such as boat hulls, buoys and ballast water tanks, but there is also a lot of research in biomedical (dental and medical) and food science applications covering bioadhesion and biofilm formation.

In the marine environment, microbial colonization of plastic was first confirmed via culturing methods and later via Scanning Electron Microscopy (SEM) imaging in the mid-70's when bacteria and diatoms were identified alongside hydroids on microplastic and macroplastic in open ocean and coastal environments. Several decades later, incubation experiments in combination with molecular methods employing DNA sequencing examined succession on plastic and other abiotic substrates *in situ* and provided the first glimpse of the taxonomic composition of microbial communities that colonized plastic surfaces directly submerged in the marine environment. While the sophistication of the different culture-independent methods has matured over time, this incubation

Fig. 1 Examples of Plasticsphere members include: (a) heterotrophic flagellated protists such as choanoflagellates scale bar=2 μm ; (b) secondary bacterial colonizers of an empty diatom frustule, scale bar=1 μm ; (c) a field of “pit-forming” microbes appearing to be engaged in plastic degradation of the polymer surface via excretion of extracellular enzymes or metabolic products that etch the plastic surface, scale bar=10 μm ; and (d) diatoms growing in the crevices of a piece of microplastic, scale bar=20 μm .

approach has allowed microbiologists to observe changes in community succession and their relation to polymer type, duration, season, geographic location and environment. Such molecular ecology studies have been published and described for a variety of plastic types and are summarized in Table 2.

From these efforts emerge some general observations that can characterize the state of knowledge of colonization of plastics in the marine environment: (1) There is a clear succession that occurs on plastic materials that are introduced into the marine environment that involves shifts in dominance of major groups of bacteria and eukaryotes (particularly photosynthetic bacteria and photosynthetic eukaryotes) over time scales ranging from hours to months; (2) Colonization studies that employ molecular approaches are limited by the available biomass that colonizes the surfaces, especially early in the process (this is also a limitation for studying biofilm communities on very small pieces of microplastic in general); (3) Many factors influence the observed results including size of the plastic piece used in the incubation experiment, its composition, the form of the control substrate, surface texture or degree of rugosity, geographic location, physico-chemical conditions, and season. For example animal larvae and microinvertebrates can settle on cm-sized fragments of plastic but would be less inclined to do so on micron and mm-sized fragments and this can influence biofilm composition. Other variables in the natural environment include the exposure to UV and mechanical action (including ingestion and defecation by marine organisms), the extent to which the plastics have been submerged in the marine environment (i.e. time), and the location in the water column or sediments where the plastics have resided (i.e. photic zone vs. mid-waters vs. sediments). One important observation in the wild is the importance of biofilms and biofouling communities in determining the fate of floating plastics in the ocean. A significant amount of plastics that float (especially PE and PP) have been detected in sediments. They are probably transported by marine snow and fecal pellets, and in addition, biofilm formation can increase the density of PMD. All of these mechanisms have been suggested as a reason for the presence of plastics that float in oceanic compartments below the surface, but the timeframes of this flux into the sediments is not well understood. All of these uncertainties make it difficult to extrapolate the results of experiments to the fate of microplastics and macroplastics in the natural environment.

Fomite Potential in the Plasticsphere

One of the first descriptive studies employing microscope images of algae in the Mediterranean unveiled an important discovery: macroplastics could carry harmful algal blooming species such as the Paralytic Shellfish Poisoning (PSP)-producing dinoflagellate *Alexandrium taylori*. Subsequent studies have expanded the list of possible nuisance microalgae bloomers attached to PMD, to include the diatom *Ceratoneis closterium* that secretes nuisance mucilage that affects fishing and tourism.

One of the first studies to employ high-throughput DNA sequencing methodologies to characterize plastisphere communities in the open ocean made another important discovery: relatively high abundances (up to 24%) of the total microbial community on a piece of PMD in the North Atlantic was *Vibrio* bacteria, implicating plastic as a possible fomite transporting potential pathogens in marine environments. Subsequent studies employing culture-dependent techniques in the North and Baltic Seas isolated several species of *Vibrio* on 13% of their collected microplastics, including potential human pathogens such as *V. parahaemolyticus* responsible for gastrointestinal disease in humans. An unknown aspect of the fomite potential of plastics is the source of the harmful microbes: whether these pathogenic or HAB hitchhikers attach to plastic in coastal areas and then become swept up in ocean currents to potentially cross entire ocean basins. The change in biofilm communities attached to microplastics as they shift from freshwater sources (rivers and streams) to more marine estuaries and ultimately the open sea is an understudied aspect of Plastisphere research that warrants further investigation.

Future Outlook

The challenges associated with reconstructing the natural history of the Plastisphere community over time and space based on studies that characterize stages of colonization point to the following future research needs (Fig. 2): (1) A better understanding of the role of microbes in ingesting PMD in the nano and micron-sized fractions and how this may get transferred up the food web via ingestion by animals: that is, the connection between the microbial food web and higher trophic levels with respect to PMD; (2) The role of biofilms on the mobilization of persistent organic pollutants and metals that adsorb to the surfaces or additives in plastic and their transfer to higher trophic levels; (3) The turn-over rate of organisms living in the Plastisphere and how long they can survive in transit (particularly with respect to potential pathogens and HABs); (4) The role of viruses in the Plastisphere and their transfer to new environments via microplastics; and, (5) The extent to which biofouling via biofilm development is responsible for the sinking of otherwise positively buoyant plastics in the water column and to what extent they contribute to the missing plastic in the ocean.

Fig. 2 A schematic diagram showing microbial interactions with PMD and possible impacts on different ocean compartments and at different trophic levels.

Degradation or Biodegradation?

The topic of degradation of plastics in the environment is a timely one that has mobilized the microbiology community, particularly in light of recent interest in applying biotechnological solutions to the growing environmental problem of plastic pollution. The focus of this section will be microbial plastic biodegradation with the important caveat that the terms degradation and biodegradation are not interchangeable. The term biodegradation refers to the complete breakdown of plastic into CO₂, H₂O, and biomass in aerobic settings and CO₂, CH₄, and biomass in anaerobic settings, in a reasonable timeframe (i.e. >90% carbon converted to CO₂ within 180 days in an industrial composting facility; at least 30% carbon converted to CO₂ within 180 days at 30°C in marine environments). Industrial composting facilities maintain a controlled biodegradation environment, but plastic in the ocean ends up on many different uncontrolled environments, and very few of them correspond to the 30°C standard for marine environments. This point is very important since, as noted in a recent European Commission Report, “in theory, almost all materials ultimately may biodegrade, even in the open environment though some will do so only after sometimes hundreds of years or more”. As a result of differing interpretations of these separate concepts, several peer-reviewed articles mention microbial “biodegradation” when they are really describing microbial degradation. Weight loss, carbonyl index, biofilm formation, and oxygen evolution are sometimes used to quantify biodegradation, but only CO₂ production is considered proof of direct biodegradation measurement according to standards organizations such as ASTM, CEN and ISO.

Fragmentation in the marine environment almost certainly is dominated by physical mechanisms including weathering due to UV radiation, mechanical, thermal, and chemical action. Microbial biodegradation and degradation in most marine environments is a much slower process. UV and mechanical weathering often precede microbial action on polymer surfaces, but once formed, microbial biofilms are thought to shield polymers from UV penetration, thereby preventing further polymer chain scission and abiotic degradation. Among early colonizers of plastic surfaces are cyanobacteria and eukaryotic phototrophs such as diatoms that may serve to oxidize the surface of plastic making the polymers more susceptible to other types of degradation. In addition to microbial adhesion and growth on plastic that may contribute directly to the surface degradation, the action of predators chewing plastic contributes to mechanical breakdown. There is evidence that the formation of a microbial biofilm contributes to the settlement of marine larvae and that microbes and larvae both make the plastic smell and taste like food for higher trophic levels. Accelerated fragmentation was initially considered beneficial to speed breakdown of plastic in the environment, but with recognition that plastic is interacting with organisms at all levels of the food web, the distinction between fragmentation and biodegradation has become more important. Plastics that contain pro-oxidant additives (PACs) have recently come under fire in the European Union due to unknown environmental impacts associated with their fragmentation in the marine environment. It is sometimes difficult to determine, even in the peer-reviewed literature, what form of plastic is being employed in research projects, and this can complicate interpretation and comparison of different studies.

The most convincing measures of environmental biodegradation follow methods that have been vetted by standards organizations such as ASTM, ISO and CEN. The ASTM standard D7081 (water) and the test method ASTM 7991 (sediment) rely on respirometry (evolved CO₂) to measure biodegradation of plastic in the marine environment. The microbiological testing that led to the development of ASTM D7081 involved a three-tiered approach and a defined consortium of microbes including bacterial species within *Alteromonas*, *Xanthomonas*, *Bacillus*, *Pseudomonas*, and the Actinomycetes. This standard also allows for the use of a natural seawater inoculum instead of a defined microbial consortium. A seawater inoculum is what is most frequently employed in testing nowadays. As of 2018, however, ASTM D7081 is under revision and requires reinstatement. Some of the concerns regarding this standard test method is that it doesn't take into account the range of temperatures and other physico-chemical conditions encountered in the marine environment (for example, the current tests are done at 30°C in the dark). It must be emphasized that the goal of biodegradation standards is to determine the inherent biodegradability of a given plastic polymer, not to provide a license for littering. Even certification agencies like Vinçotte in Belgium with their “OK-Marine” do not allow products that are commonly littered to carry this label since they acknowledge that the marine environment is not an appropriate disposal environment for plastics and none of these standards are designed to unintentionally imply that plastic released into the environment is acceptable if the standard is met.

Bio-based plastics that have been shown to biodegrade in the natural environment include: polyhydroxyalkanoates (PHA) and their derivatives: poly-3-hydroxybutyrate (PHB), poly-hydroxyvalerate (PHV), as well as the poly(α -hydroxy acids): polylactic acid (PLA) and polyglycolic acid (PGA). PHA, PHB, and PHV are examples of bio-based plastics that are microbial in origin. PLA and PGA can be synthesized from bio-derived monomers or petroleum sources so are examples of biodegradable plastics that are not always bio-based. Additional petroleum-based aliphatic polyesters that are biodegradable include polybutylene succinate (PBS), polybutylene succinate adipate (PBSA), and polycaprolactone (PCL), as well as modified derivatives of polyethylene terephthalate (PET) and polybutylene terephthalate (PBT), aromatic polyesters such as polybutylene succinate terephthalate (PBST), polybutylene adipate terephthalate (PBAT), and polytetramethylene adipate terephthalate (PTMAT). Many of these polymers are used in the medical industry for drug delivery, but others have a variety of applications beyond the scope of this review. Several biodegradable plastics are better recognized by their commercial names such as Mirel (PHA) - Metabolix, EcoPLA (PLA) - NatureWorks, EcoFlex (PTMAT) - BASF, and Mater-Bi - Novamont. In many cases, polymer blends (with bio-based, biodegradable and non-biodegradable components) are created that possess the desired characteristics, so methods exist that help determine the so-called biogenic carbon present in a given plastic.

Genomics and transcriptomics are informing the mechanisms of plastic biodegradation with PHA being one of the best-studied examples. Genes such as b-ketothiolase (*PhaA*), acetoacetyl-coenzyme A reductase (*PhaB*), PHB polymerase (*PhaC*), and PHB depolymerase (*PhaZ*) are involved in both the synthesis and degradation of PHB in *Rhizobium eutropha* while *Pseudomonas putida* is known to possess PHA depolymerase. Since PHAs are biopolymers that microbes can both synthesize and degrade, it is important to understand that there are intracellular and extracellular PHA depolymerases. The bacterial PHA-degrading phenotype involves secretion of extracellular depolymerases, but also successful biodegradation depends on the degree of crystallinity of the bioplastics as well. Some bacteria possess multiple depolymerases capable of degrading a suite of different types of PHAs. More than 300 microbial species can produce PHAs but there are likely many more. Well-studied species include *Alcaligenes latus*, *Chromatium vinosum*, *Cupriavidus necator*, *Bacillus megaterium*, *Pseudomonas putida* and *P. lemoignei*, and archaeon *Haloferax mediterranei*. Likewise, there are many bacteria and fungi capable of biodegrading PHAs and there are likely protists yet to be characterized that do as well. As a result, some argue that currently this class of bio-based plastics are the only truly biodegradable ones in the marine environment.

Future Outlook

The role of microbes in degradation of plastics in the environment cannot be denied, but their abilities to completely biodegrade polymers is generally overstated. The recent reports of plastic metabolizing microbes in various industrial settings, and pit-formers on the surface of open-ocean microplastics lead some to make false claims of a microbial solution to a global problem. In this and other examples, partial degradation of plastics in any environment may lead to more harm than good as the microbial food web incorporates these small pieces of recalcitrant polymers up the food chain where they can biomagnify. While microbes can address many biotechnological challenges - they are not the final solution to all problems, particularly that of marine litter. Recent discoveries of microbe-wielding mealworms capable of consuming polystyrene and PET-degrading bacteria need to be tempered with alternative solutions including those that address appropriate plastic uses and global waste management infrastructures that currently allow too much plastic to enter our oceans.

Glossary

Cis-acting element A specific DNA sequence which is present within the promoter or enhancer elements of genes, to which transcription factors bind and regulate the expression of genes on the same chromosome.

Coding region A portion of DNA that is transcribed into mRNA and translated into proteins.

Coding region A portion of DNA that is transcribed into mRNA and translated into proteins.

Oncogenic Causing or tending to cause the formation and development of tumors.

Papillomavirus A group of small DNA viruses that cause papillomas in various animals and is responsible for human genital warts.

Polyomavirus A DNA tumor virus with a very small genome that infects animals and humans.

Regulatory element A promoter, enhancer or other segment of DNA where regulatory proteins such as transcription factors bind preferentially and control gene expression.

Regulatory region A region of a chromosome that controls gene expression.

Replication The action or process of duplication of DNA.

TATA box DNA sequence found in the promoter region of most genes in eukaryotes, to which basal transcription factors bind and initiate the process of transcription by RNA polymerase.

Transcription A process by which genetic information on a strand of DNA is used to synthesize a strand of complementary RNA.

Transcription factor A protein that binds to specific segments of DNA using the DNA binding domain.

Abbreviations

AP-1	Activating protein-1
BKV	BK virus
BPV-1	Bovine papillomavirus-1
CMV	Cytomegalovirus
CNS	Central nervous system
CR1	Conserved region-1
CR2	Conserved region-2
E1	Early protein-1
EGF	Epidermal growth factor
ER	Endoplasmic reticulum
GRS	GC-rich element
HHV-6	Human herpesvirus-6
HPV	Human papillomavirus
HPyV12	Human polyomavirus-12
HPyV6	Human polyomavirus-6
HPyV7	Human polyomavirus-7
HPyV9	Human polyomavirus-9
IE2	Immediate-early transactivator 2
JCV	JC virus
KIPyV	Karolinska Institute polyomavirus
LCR	Long control region
LT-Ag	Large T antigen
MAP	Mitogen activated protein
MBP	Myelin basic protein

VLP	Virus like structures
WUPyV	Washington University polyomaviruses

Polyomaviruses

Classification

Polyomaviruses are classified within the polyomaviridae family and are comprised of small tumor viruses that infect a number of species, including human, mouse, monkey, hamster, baboon, rabbit, and bird (Table 1). Their genomes are a single molecule of covalently closed, super helical double stranded DNA that replicates in the nucleus (Figure 1, a typical genomic organization of the polyomaviruses is exemplified by the JC virus genome). All family members form capsids but in similar size. Capsids are mainly composed of three capsid proteins, VP1, VP2, and VP3 although production of a fourth capsid protein has been recently reported

Table 1 Polyomaviruses were isolated from different species, including humans, monkey, mouse, hamster, baboon, rabbit and bird

<i>Virus</i>	<i>Host species</i>
Simian virus 40 (SV40)	Rhesus Monkey
Polyomavirus (PyV)	Mouse
JC virus (JCV)	Human
BK virus (BKV)	Human
KI virus (KIPyV)	Human
WU virus (WUPyV)	Human
MCPyV	Human
HPyV6	Human
HPyV7	Human
HPyV9	Human
HPyV10	Human
MWPyV	Human
MXPyV	Human
HPyV12	Human
K papovavirus (KPV)	Mouse
Hamster papovavirus (HaPV)	Hamster
Stump-tailed macaque virus (STMV)	Stump-tailed macaque
Lymphotropic papovavirus (LPV)	African green monkey
Budgerigar fledgling disease virus	Bird
Simian agent 12 (SA12)	Baboon
Rabbit kidney vacuolating virus (RKV)	Rabbit

Figure 1 JCV genome shows a bidirectional expression pattern. Early coding region encodes regulatory proteins, LT-Ag, Sm t-Ag and T' proteins (T'₁₃₅, T'₁₃₆ and T'₁₆₅). Late coding region encodes regulatory (agnoprotein) and structural proteins (VP1, VP2, and VP3). Control region contains origin of DNA replication (ori) and promoter/enhancer elements for early and late promoters.

within the family for SV40. Their genome is about 5000 base pairs and exhibits a similar genomic organization and regions within their genomes are highly conserved, suggesting that family members are descended from a common ancestor. Despite the high genomic similarity, most of the family members display a narrow host range and do not productively infect other species (Table 1). In addition, some family members induce tumors in experimental animals, including mice, hamsters and monkeys.

Among the polyomavirus family, polyoma (referred as mouse polyomavirus here in) was the first family member to be discovered. Ludwig Gross was studying the transmission of murine leukemia virus in mice and extracts from infected animals could be used to transmit leukemia. It was surprising that some of the animals developed salivary gland tumors rather than leukemia. Further studies by Gross demonstrated that two agents, the one that caused salivary gland tumors and the other that caused mouse leukemia could be separated on the basis of differences in their filtration, sedimentation ability (the murine leukemia virus (MuLV) turned out to be larger in size) and heat inactivation properties (MuLV can be inactivated completely at 65 °C whereas the agent that cause salivary gland tumors was insensitive to heat inactivation at the same temperature). The virus that caused salivary gland tumors was then isolated and named mouse polyomavirus because of its characteristics to cause a variety of tumors in different tissues in new born mice. Adult mice, however, do not usually support the formation of tumors when infected with the same virus.

SV40 is among the viruses that were identified through screening of secondary rhesus monkey kidney cells, which were being used for production of polio vaccine. SV40 normally does not cause cytopathic effect on infected cells. However, when African green monkey kidney cells were infected with extracts from the rhesus kidney cell cultures, the cells produced a pronounced cytopathic effect, which led the investigators to further study the cause. It turned out that that cytopathic effect was caused by viral infection, namely SV40. Contamination of a considerable amount of polio vaccine stock vials with live SV40, inoculation of some of those in the general public during the late 1950s and early 1960s raised a concern among the scientific community, because the oncogenic potential of this virus had been demonstrated in experimental animals, for example, in new born hamsters. It was thought that it may also do so in humans. Studies were intensified to determine the risk factor of SV40 to be a causative agent for induction of tumors in humans but such efforts did not show a significant association with the increased rates of ependymomas and osteosarcomas or mesotheliomas or brain tumors. The detection of SV40 LT-Ag genome in these cancer types in general population, however, have led to the renewed interest in the possibility that SV40 may be involved in the induction of some human tumors.

Human polyomaviruses, JC virus (JCV) and BK virus (BKV) were the first to be discovered in 1971. JCV was isolated from a brain tissue of a PML patient by overlaying infected extracts over the primary cultures derived from human fetal brain. The virus was then

successfully cultivated from those long-term cultures. This also demonstrated the first direct evidence that a neurotropic virus was associated with the development of PML. In the same year, a virus similar in structure was isolated from the urine of a patient who underwent a renal transplantation. Both viruses were named with the initials of donors, JCV for a patient with PML and BKV for a patient, who underwent renal transplantation. JC virus causes a fatal demyelinating disease of the central nervous system (CNS), which is known as progressive multifocal encephalopathy. BK virus can cause organ loss in renal transplant recipients, which is the medical condition, described as 'the polyomavirus-associated nephropathy' (PVN).

Eleven new human members of polyomavirus family have recently been discovered; one was isolated from a human respiratory tract samples by PCR amplification and named KI polyomavirus (KIPyV); and the other was isolated from a patient with symptoms of acute respiratory tract infection and named WU virus (WUV). Follow up studies do not so far conclusively support an evidence for the association between infections with WU and KI polyomaviruses and respiratory tract diseases. Another polyomavirus was isolated from the merkel cell carcinoma (a rare neuroendocrine skin tumor) by pyrosequencing of the cDNA made from the host transcripts followed by bioinformatic subtraction analysis of the host sequences and was named merkel cell carcinoma-associated polyomavirus (MCPyV). The other one was isolated from 'Trichodysplasia Spinulosa' samples by rolling circle amplification of the viral genome with specific primers followed by DNA sequence analysis and was named Trichodysplasia Spinulosa-associated polyomavirus (TSPyV). The rest of the recently discovered human polyomaviruses, including HPyV6, HPyV7, HPyV9, HPyV10, MWPyV, MXPpyV, and HPyV12 were isolated from either serum of a patient or stool or skin samples but were not yet definitively linked to with a particular human disease.

The oncogenic potential of polyomaviruses is one of the major driving forces behind the further study of the biology of these viruses. In addition, the small genome size and easy growth in culture made these viruses (particularly SV40) as suitable model systems to examine many fundamental questions in eukaryotic molecular biology. Many major discoveries have been made in this sense using these viruses, including the structure of supercoiled DNA, the identification of eukaryotic origins of DNA replication, discovery of alternative splicing, organization of promoters and enhancers and their involvement in gene expression and understanding of the mechanisms of negative and positive regulation of gene expression. Studies of the biology of these viruses also led to discoveries related to the cell cycle regulation, oncogenesis and tumor suppressor genes. In this article, we devote a special attention to the biology of human polyomavirus JCV and simian virus SV40.

Virion Structure

Polyomavirus family members all form capsids, which are composed of three viral proteins, VP1, VP2, and VP3. The viral genome, which is a double stranded circular DNA, complexed with cellular histones, H2A, H2B, H3, and H4 in the form of chromatin is surrounded by capsid proteins. It is estimated that outer shell of the capsids are made up of VP1, organized into 72 pentamers (in the case of SV40), and each pentamer associates with a single VP2 and VP3. VP1 shows the ability form pentamers when produced in either *Escherichia coli* or baculovirus systems. These pentamers form virion like structures in the absence of the other two-capsid proteins (VP2 and VP3). It appears that these pentamers forms flexible structures, which allow all capsid proteins and the viral genome to fit together and make an icosohedral capsid structure. Calcium ions are required for the stability of pentamer–pentamer interactions. There are no disulfide bonds formed within the pentamer subunits, but they can form between adjacent pentamers, which is evident from the fact that reducing agents are required for disassembling virus particles. The sequences of minor capsid proteins, VP2 and VP3 completely overlap and these two proteins form the second layer in the polyomavirus capsid shell. The C-terminus region of the minor capsid proteins is most conserved within the polyomavirus family and this is the region that interacts with the N-terminus of VP1. When the capsid proteins are produced in the cytoplasm, they are transported into the nucleus where the encapsidation of the virions takes place. Although the process by which viral DNA is encapsidated into the virions is totally unknown, there are reports suggesting that viral late regulatory protein, agnoprotein, may play a major role, directly or indirectly in the process by regulating the interaction of capsid proteins with viral DNA.

Genomic Organization

The genome of all polyomaviruses is composed of bidirectional regulatory elements (Figures 1 and 2(a) and 2(b)) and coding regions. The regulatory region of each genome contains the origin of DNA replication and promoter/enhancer elements (Figure 2). Due to space restrictions, only the genomes of JCV and SV40 have been described in detail here, but others were either briefly mentioned or referred to the further readings. In the case of JCV, the regulatory region exhibits hypervariability in its sequence composition. That is, although two 98-bp tandem repeats are a characteristic of Mad-1 strain of JCV, there are considerable deviations from this characterization in other strains of JCV. For example, the regulatory region of Mad-4 strain contains two tandem repeats which are only 84-bp in length, whereas that of archetype strain contains only one 98-bp repeat with two insertions, 23-bp and 66-bp. JCV archetype regulatory region is thought to be more adaptive to a latent infection and, upon reactivation, virus undergoes a deletion/duplication process within its regulatory region, through which apparently gains the ability to become a more virulent virus to infect oligodendrocytes.

In the case of SV40, the regulatory region also contains repeated DNA elements, which work as enhancers for the viral gene expression. The two 72 base-pair repeats and the three GC-rich 21 base-pair repeats are the main characteristics of the SV40 regulatory region. These DNA elements are located at the late site of origin of the DNA replication with respect to late coding region

Figure 2 Promoter and enhancer elements of the control region of JCV and SV40. (a) Control region of JCV contains origin of DNA replication (ori) and promoter/enhancer elements. Two-98-bp tandem repeats is a characteristic of Mad-1 strain of JCV. *Cis*-acting elements including nuclear factor kappa B binding element (NF-κB), pentanucleotide element (Penta), nuclear factor 1 binding element (NF-1), GC-rich element (GRS), activating protein 1 binding element (AP-1) serve as binding sites for many transcription factors. Transcription factors that have been shown to bind the promoter/enhancer elements are shown at the lower part of the figure. Approximate location of LT-Ag antigen binding sites and Tat responsive elements are indicated. A portion of the control region was subdivided into arbitrary sub regions, including A, B, C, D, E, F and G to define more easily the locations of the different *cis*-acting element. (b) Schematic representation of SV40 control region. Twenty-one base pair (21 bp) and 72 bp repeats are the characteristics of SV40 control region. As shown for JCV control region (panel A), SV40 control region also contains the origin of viral DNA replication and many *cis*-acting elements, which serve as target sites for many transcription factors, including NF-κB and Sp1.

SV40 (Figure 2(b)). The bidirectional nature of the regulatory elements of the polyomaviruses may provide an advantage to each virus to efficiently transcribe their genes, but the mechanism of which is currently unknown.

The coding region of polyomaviruses has two directions, early and late, for transcription. Transcription extends directionally from initiation sites near the origin to produce the early and late messenger RNAs (mRNAs). They are transcribed from the opposite strands of the viral genome. The early region of JCV, for example, encodes only regulatory proteins including LT-Ag, Sm t-Ag and T' proteins (T'135, T'136, and T'165). Similarly, the early region of SV40 encodes two main regulatory proteins, LT-Ag and Sm t-Ag. In addition, this region of SV40 also encodes a 17KT protein. Moreover, Polyoma and closely related viruses encode three T antigens, LT-Ag, middle T (MT-Ag) and Sm t-Ag. All of the T antigens of each polyomavirus, at least JCV, BKV, SV40 and polyoma, share N-terminal sequences but contain different C-terminal regions. The pre-mRNA encoded from the early region of each virus is alternatively spliced to produce the mRNA that encodes these proteins.

The LT-Ag of all polyomaviruses is the main regulatory protein of polyomaviruses (Figure 3). It is absolutely required for the replication of the viral genome. It also transactivates the late promoter and auto regulates its own promoter (early promoter). Sm t-Ag on the other hand, although the precise function of it is unknown, also play regulatory roles in the viral replication cycle. Along with the LT-Ag, it pushes the cells into the S-phase of cell cycle, during which all DNA viruses including polyomaviruses replicate their DNA. The function of the T' proteins (T'135, T'136, and T'165) in the viral life cycle, which are specifically transcribed from the early genome of JCV, is unknown, although recent evidence suggests that they may have roles in cell transformation. The MT-Ag of polyoma appears to behave much like Sm t-Ag during the viral replication cycle. That is, it does not participate directly in the replication of viral DNA as LT-Ag does, but rather it contributes to the conditioning of the infected cells by activating some of the genes that are required for S-phase entry.

Contrary to the early region, the late region of JCV, BKV and SV40 encodes a mixture of structural (capsids, VP1, VP2 and VP3) and regulatory (agnoprotein) proteins (Figure1). The mouse polyomavirus, however, only encodes structural, not regulatory proteins from its late coding region (VP1, VP2 and VP3). Alternative splicing of the late common pre-mRNA also produces the mRNAs for the late gene products. VP2 and VP3 sequences overlap but VP3 sequences are a subset of VP2 sequences (Figure 1). The late region of monkey (SV40) and human (JCV and BKV) polyomaviruses encodes a small, basic regulatory protein, called agnoprotein. This small protein is encoded by the leader region of some species of the late viral mRNA and accumulates mostly around the perinuclear region. Null mutants of this protein in JCV and SV40 result in fewer progeny virions and PKC-phosphorylation mutants of this protein exhibit even more severe phenotypes in JCV, which are totally defective in viral life cycle. In other words, the virus with phosphorylation mutants of this protein is unable to continue the viral life cycle due to empty capsid formation, suggesting that the agnoprotein is actively involved in JCV virion biogenesis. The same is perhaps true for SV40 and BKV. The other polyomaviruses, including KIPyV, WUPyV, MCPyV TSPyV HPyV6, HPyV7, HPyV9, HPyV10, MWPyV, MXPpyV

Figure 3 SV40 large T-antigen contains several functional domains. They include the binding regions to polymerase α -primase (Pol α), tumor suppressor proteins Rb and p53, human heat shock protein 70 (hsc70) and coactivators p300 and CBP. ATPase activity domain, DNA binding domain, nuclear localization signal (NLS) domain, helicase domain, Zn finger domain, host range domain, and J domain are also depicted.

and HPyV12 do not contain an open reading frame for the agnoprotein and replicate in tissue culture *in vitro* well suggesting that that if the agnoprotein is provided in trans, these viruses may replicate sufficiently in appropriate cell culture systems. JCV agnoprotein was recently found to form highly stable dimers and oligomers *in vitro* and *in vivo* through its amphipathic α -helix domain located between amino acids 23 and 39. The α -helix domain of the protein plays critical roles in function and stability of the protein, which can be exploited for drug discovery purposes against JCV-induced progressive multifocal leukoencephalopathy (PML).

As opposed to the regulatory region, the coding regions of JCV show a significant sequence homology to BKV and SV40 (70–80%). The sequences within the regulatory region of each virus are considerably divergent from one another. This divergence mostly determines the tissue or species-specific replication of each virus. In other words, the regulatory region is mainly responsible for the tissue-specific expression of each virus, although LT-Ag, at least in the case of JCV, is also known to contribute to this unique expression. Moreover, the tissue-specific cellular factors also appear to be critical for the unique expression of each viral promoter. For example, *in vivo* and *in vitro* transcription assays as well as cell-fusion experiments have clearly indicated that there are positively and negatively acting transcription factors responsible for the expression of the JCV genome in glial and non-glial cells respectively. For instance, it was shown that the JCV early promoter expressed well in glial cells. However, when glial cells are fused with fibroblasts to form heterokaryons, early gene expression is significantly reduced in heterokaryons, suggesting that there are positively and negatively acting factors in glial and in non-glial cells respectively.

Structural organization of the regulatory region

The regulatory region of polyomaviruses exhibits the most divergent region among the family members and is responsible for the tissue specific expression of each family member, although LT-Ag also contributes to this specificity. The promoter/enhancer elements and origin of DNA replication are the common elements present with the regulatory region of each the family member, however, the structural configuration of these elements exhibits significant divergence from one strain to another one within each member or one member to another within each family. For example, the Mad-1 strain of JCV contains two 98-bp repeats within its control region, which is a prototypic property of this strain. Other strains of JCV, such as the archetype strain and Mad-1 strain, however, show significant divergence from this property. The regulatory region of the Mad-1 strain of JCV and that of SV40 are schematically shown in Figure 2. Origin of the DNA replication is the only region in the regulatory region of each family member, at least between JCV, SV40, and BKV, which shows substantial sequence homology among the family members. Other regions are quite divergent between these three viruses. Each repeat of the regulatory region of the Mad-1 strain of JCV contains a TATA box located in the early side of the individual repeats and first TATA box with respect to origin of DNA replication appears to be involved in the positioning of the transcription start sites for viral early genes. The second TATA box, however, does not have a similar function for the viral late genes. The other enhancer elements including penta, AP-1 and NF-1 follows there after TATA box. They are important DNA elements for the regulation of JCV promoters. These elements are targets for several transcription factors and contribute to tissue tropism. The major *cis*-acting elements and transcription factors that bind to those regions are illustrated in Figure 2.

Enhancer elements and cellular transcription factors involved in viral regulation

Many cell type-specific and ubiquitous factors are involved in the expression of the polyomavirus early and late promoters. These factors directly or indirectly interact with the enhancer elements present in the regulatory region and regulate viral gene expression. For the simplicity of the description of those factors, we focus on those, which are involved in JCV regulation. LT-Ag and agnoprotein are two regulatory proteins, which play critical roles in the regulation of JCV promoters. LT-Ag is the initiator of JCV DNA replication. It binds to the origin of DNA replication in double hexamer configuration, unwinds it, and the replication fork proceeds in bidirectional manner in the presence of the cellular factors that are required for this process. With respect to its role in transcription, studies also showed that while LT-Ag autoregulates its own transcription from the viral early promoter, it significantly activates the late promoter, resulting in the expression of agnoprotein and viral capsid proteins. In addition to LT-Ag and

agnoprotein, Sm t-Ag of polyomaviruses is also involved in viral regulation. Although the precise function of it is unknown, at least in JCV case, a stop codon mutation at Ser90 was observed to negatively but significantly affect the virus yield.

There are multiple enhancer elements present in the regulatory region of polyomaviruses. A close inspection of regulatory regions of JCV, for example, revealed the presence of multiple enhancer elements, which are targets of many cellular transcription factors (Figure 2), which include, NF- κ B, GRS, penta, NF-1, AP-1, and 'AP-1 like' motifs. In addition to those, Tat responsive elements and LT-Ag binding sites are also present. The entire regulatory region of JCV, for the sake of the simplicity of the description of JCV regulatory elements and transcription factors that targets those sites, is divided into arbitrary regions including A, B, C, D, E, F, and G (Figure 2). NF- κ B element, which is located at the early site of the promoter with respect to the origin of DNA replication is a target of stress inducible transcription factor, NF- κ B. This factor represents a large family of transcription factors, which are inducible in response to a wide variety of extracellular stimuli including cytokines, phorbol esters, and viral infection. Two constitutively expressed subunits of NF- κ B, p50 and p52, activate transcription from D domain, while another subunit of NF- κ B, p65, regulates the transcription of JCV through NF- κ B motif itself. A 23-bp element, which is present within the regulatory regions of many JCV variants, including archetype and Philadelphia-1 strain of JCV is also targeted by NF- κ B family members. The GRS sequences, which are present within the G region of the viral promoter, serve as binding sites for another inducible cellular factor GBP-i, which suppresses viral late promoter activity in reporter promoter assays. The A and C regions contain binding sites for a member of well-characterized tissue-specific and developmentally regulated POU family of transcription factors, for example, Tst-1. This factor regulates JCV transcription from viral early and late promoters. It also interacts with the JCV LT-Ag and synergistically activates the viral early and late promoters. GC-rich sequences which are located within pentanucleotide region of JCV appears to be a target for a ubiquitously expressed transcription factor, Sp-1, which was found to activate gene expression from the viral early promoter. Another important regulatory element present in the control region of JCV is 'nuclear factor 1' (NF-1) binding sites, which are scattered within the regulatory region including arbitrary sites, B, D, and E. NF-1 is involved in both regulation of JCV transcription and replication. B region contains target sites for several factors, including GF-1, YB-1, Pur α , and AP-1. GF-1, a human homologue of the murine Subp-2 protein, transactivates viral early and late promoters. Two well-characterized cellular transcription factors, YB-1 and Pur α , regulate viral gene expression and replication through interaction with LT-Ag. An additional binding site for YB-1 is also present in the JCV regulatory region, which is localized to arbitrary region E. BAG-1, a ubiquitously expressed cellular factor, interacts with Bcl-1 and regulates JCV promoters through the NF-1 binding site. Another inducible factor that interacts with B region is c-Jun, which is a member of the AP-1 family of transcription factors. The family members are known as the immediate early inducible protooncogenes and are critical for the expression of many cellular and viral genes. C-Jun functionally interacts with LT-Ag and is phosphorylated during the JCV life cycle in an infection cycle-dependent manner. Besides the above-described cellular and viral regulatory proteins, the JCV regulatory region is subject to cross-regulation by the regulatory proteins that are encoded by other viruses including immediate-early transactivator 2 (IE2) from cytomegalovirus (CMV) and Tat from HIV-1

Life Cycle

The infection cycle of polyomaviruses starts with the attachment of the viral particles to the cell surface receptors (Figure 4). The serotonin receptor 5HT_{2A} as well as α (2–6)-linked sialic acid were shown to be critical for the attachment of JCV to the cell surface. Gangliosides play an important role in the attachment of both SV40 and mouse Polyomavirus on the cell surface. BKV, on the other hand, appears to use α (2,3)-linked sialic acid and gangliosides (GD1b and GT1b) as cell surface receptors for attachment. The attached polyomavirus particles enter the cells through either caveolae-mediated (BKV and SV40) or clathrin-mediated (JCV) or cell type specific (Polyoma) endocytosis pathways. Figure 4 highlights the chain of events step by step during the life cycle of a polyomavirus. Following internalization, the viral particle is transported to the endoplasmic reticulum, at least in the case of SV40, for uncoating of the capsid and viral DNA is transported into the nucleus by an unknown mechanism. The next step in the viral infection cycle is the expression of the viral early genome in the nucleus. Viral transcripts undergo splicing events before they are transported back to the cytoplasm for translation. Translation of early transcripts results in the production of viral early regulatory proteins. In the case of JCV, this results in the production of large T antigen (LT-Ag), small t antigen (Sm t-Ag) and T' proteins (T'135, T'136 and T'165). LT-Ag is then transported back to nucleus to initiate viral DNA replication and to trans-activate the viral late promoter for the production of regulatory agnoprotein and three structural capsid proteins, VP1, VP2 and VP3 (Figure 1). Upon translation, capsid proteins are transported to the nucleus and the encapsidation process starts. It appears that the capsid proteins are sequentially added to and arranged on the viral genome to package the viral DNA into the capsids. The final step in the viral life cycle is to release the virions from infected cells. Although the mechanism of this process is not known, it is likely that they are released upon the lysis of the infected cells.

Cross-Regulation of JCV Promoters and JCV Reactivation

Impaired cellular immunity is a predisposing condition for the reactivation of JCV and the onset of PML. Lymphoproliferative disorders used to be the predominant underlying factor for the reactivation of JCV from latency. In recent years, however, due to the AIDS epidemic, this trend has changed and a strong association of PML with AIDS has been established. The statistical data in this regard suggest that 5–10% of AIDS patients eventually develop PML. However, there is a discrepancy between the degrees of the reactivation of JCV in AIDS patients versus in those with other immunosuppressive conditions. In other words, JCV is reactivated relatively more often in immunosuppressed AIDS patients than in the cases of other immunosuppressive states, including in those

Figure 4 Schematic representation of JCV life cycle. Sequential events that take place during the JCV life cycle are indicated by numbers as follow: (1) adsorption of virus to the cell surface receptors; (2) entry by clathrin-dependent endocytosis; (3) transport to the endoplasmic reticulum (ER); (4) uncoating either in ER or in the nucleus; (5) transcription of early coding region; (6) translation to produce early regulatory proteins, LT-Ag, Sm t-Ag and T' proteins (T'₁₃₅, T'₁₃₆ and T'₁₆₅); (7) Nuclear localization of LT-Ag; (8) replication of viral genome; (9) transcription of viral late genome; (10) translation of viral late transcript to produce agnoprotein and capsids (VP1, VP2 and VP3); (11) Nuclear localization of capsids; (12) assembly of viral progeny in the nucleus; (13) release of virions from infected cells; (14) released virions.

with hematological malignancy, solid tumors and organ transplantation, all of which have a long period of immunosuppressive states. This suggests that there is something special about the HIV infection cases and JCV reactivation, perhaps the degree and duration of immunosuppression in HIV infection may not be the only factor for the development of PML. It could be that HIV infection affects many arms of the host defense system as opposed to one or two seen in other immunosuppressive states. In addition, other alterations including the deficiencies in chemotaxis, monocyte-dependent T-cell proliferation, Fc-receptor function, C3 receptor-mediated clearance, and oxidative burst response greatly contribute to the suppressive conditions of the immune system in AIDS patients and this in turn may facilitate JCV reactivation. As a result, it is tempting to suggest that a combination of the conditions mentioned above may have a substantial contributing effect than single case on the reactivation of JCV.

In addition to the immunosuppressive conditions, viral regulatory proteins, produced by viruses other than JCV may have a direct or indirect impact on JCV reactivation and regulation. For example, HIV regulatory protein Tat (a potent transactivator of HIV long terminal repeats) may have such a potential effect. Tat mediates its transregulatory activity through a specific RNA sequence located in the leader of all HIV-1 RNAs, called transactivation response elements (TAR). Several critical G residues within the TAR element are required for its function. Similar sequences, called Tat response elements, are also present in the regulatory region of JCV. Tat also induces transcription from the JCV late promoter through these sequences. The critical G residues required for the function of HIV-TAR are also conserved in the JCV-TAR element and play an important role in Tat-mediated activation of the JCV late promoter. Thus, the TAR homologue may participate directly in the overall activation of the JCV late promoter. Tat may also influence JCV gene expression indirectly through the activation of inducible transcription factors and cytokines, among which NF- κ B and c-Jun/AP-1 were shown to activate the JCV promoters. Taken together, the regulatory factors induced by HIV Tat or Tat-induced cytokines may directly or indirectly play regulatory roles in activation of JCV promoters.

In addition to JCV, there are several other human viruses that establish persistent infection in different tissues and organs of the human body including those such as BKV, cytomegalovirus (CMV) and human herpesvirus-6 (HHV-6). Some of the regulatory proteins produced by these viruses may also cross-regulate JCV as Tat does. CMV is, for example, highly prevalent in the human population and infects any organ of its host. It is commonly reactivated in renal transplantation and bone marrow patients. It is also

reactivated after renal transplantation in AIDS patients in the kidney, lymphoid organs, stromal cells and CD 34-positive bone marrow progenitor cells. It is reported that CMV infection positively affects the level of JCV DNA replication and transcription. JCV is known to infect only glial cells but this restricted cell specificity can be overcome if the immediate-early transactivator 2 (IE2) protein of CMV is provided to the JCV infected cells. For instance, fibroblasts can be permissive to JCV replication if this protein is present in the JCV-infected cells

The presence of HHV-6, another ubiquitous human virus, is reported in oligodendrocytes within PML lesions suggesting that JCV and HHV6 may have a common host cell. This virus establishes a life-long infection in different organs, including the urinogenital tract, the brain, the liver, the lung, and peripheral blood cells. There appears to be a high correlation between polyomavirus infection and HHV6 infection and this co-infection may have an impact on JCV gene regulation and perhaps in the reactivation process.

JCV and BKV have been known to concomitantly infect human tissues, such as the kidneys and the urinogenital tract. Additionally, both viruses were also detected in the peripheral blood cells of both healthy and immunocompromised individuals. These viruses encode very similar regulatory proteins, including LT-Ag, Sm t-Ag and agnoprotein. These proteins may well cross-regulate the replication and gene expression of each virus and may contribute to the reactivation of each virus.

Polyomavirus-Associated Diseases

Progressive multifocal leukoencephalopathy

PML is a fatal demyelinating disease of the central nervous system (CNS), which results from the lytic infection of the oligodendrocytes by the human polyomavirus, JCV. Oligodendrocytes produce the myelin sheaths, which wrap around the axons of neurons to facilitate the transmission of the neuronal current. The infection of oligodendrocytes by JCV indirectly causes the death of neurons in the white matter in CNS, because neurons depend on the support provided by oligodendrocytes for their survival. Subsequently, the loss of both oligodendrocytes and neurons in the CNS results in small plaque formation in the infected areas of the CNS. These areas, as the disease progresses, coalesce and form the characteristics of PML lesions resulting in the death of the infected individual. PML mostly develops in individuals with underlying immunosuppressive conditions, including lymphoproliferative diseases, AIDS and Hodgkin's lymphoma, in a small number of cases, it may also affect individuals with no underlying disease. PML used to be a rare complication of middle-aged and elderly patients with lymphoproliferative diseases before the AIDS epidemic. However, it is now a commonly encountered disease of the CNS particularly in HIV patients. This increase suggests that HIV infection may directly or indirectly influence the reactivation or progression of CV infection. This is supported by recent reports, indicating that the incidence of PML in HIV-sera positive patients reached up to 5%, compared to that of 0.8% before the AIDS epidemic. Furthermore, there has been an incidence of reactivation of JCV in Crohn's disease and Multiple Sclerosis patients, who underwent treatment with both interferon $\beta 1\alpha$ and natalizumab, a monoclonal antibody that selectively blocks $\alpha 4$ integrins. These incidences suggest that any immunosuppressive treatment of patients would be a risk factor for the reactivation of JCV and progression of PML.

Polyomavirus-associated nephropathy (PVAN)

JCV and BKV are the two members of the polyomavirus family that naturally infect humans. Sequences of monkey polyomavirus, SV40 were also found in different human tumors, which suggests that it may also infect humans. In kidney transplant recipients, the replication level of BKV significantly increases, when those recipients undergo immunosuppressive therapies. This leads to the lytic destruction of infected cells in the kidneys and compromises the function of the organ. This medical condition is described as 'the polyomavirus-associated nephropathy (PVAN)' and is a serious problem in 4–9% of the kidney transplant recipients.

Cell Transformation and Tumor Induction by Polyomaviruses

Many polyomaviruses including JCV, BKV, SV40, and mouse polyomavirus are known to induce a variety of tumors in experimental animals. Many also have the ability to induce neoplastic cell transformation in tissue culture. After its isolation, JCV for example was demonstrated to induce tumors in experimental animals in tissues of neuronal origin, but the type of tumor that is induced by JCV depends on the type and the age of the animal and the site of virus inoculation. For example, subcutaneous and intracerebral inoculation of JCV Mad-1 strain into newborn Syrian hamsters resulted in the formation of several types tumors, including medulloblastomas, glioblastomas, neuroblastomas in a majority of the animals (more than 80%). In contrast, intraocular inoculation of the same group of animals with the same strain of JCV resulted in abdominal neuroblastomas in several locations of the body. It was also observed that these tumors were found to be metastasized to the bone marrow, lymph node and liver in these animals.

It is interesting that JCV is the only polyomavirus that induces tumors in nonhuman primates, like monkeys. The other members of the polyomavirus family, including BKV and SV40 do not cause tumors in those animals. To evaluate a case that resembles PML in humans, owl and squirrel monkeys were inoculated with? subcutaneously, intraperitoneally, and intracerebrally. One owl monkey developed a malignant cerebral tumor similar to astrocytoma that resembles the one seen in humans, after 16 months of inoculation. Another animal developed a malignant neuroblastoma after 25 months of inoculation.

Transgenic mouse models were also used to evaluate an acute demyelination case, that is observed in PML patients. Transgenic animals were created using the promoter and coding regions for JCV LT-Ag. The phenotypes of these transgenic animals showed a mild to severe tremor phenotype and further evaluation of the animals revealed hypo- and dys-myelination in the CNS but not in

the peripheral nervous system (PNS) suggesting that expression of LT-Ag only affects the myelin formation in CNS rather than in PNS. Microscopic evaluation of the myelin sheet around the axons revealed a low level of the layer of myelin formation although the expression level of proteolipid protein (PLP), myelin basic protein (MBP) and myelin associated glycoprotein genes appeared to be normal at the RNA level. Their respective protein levels, however, were reduced. This suggests that LT-Ag influences the rate of the translation of mRNA for those genes rather than their transcription.

JCV genome has also been detected in a variety of human tumors, which raises a possibility of the involvement of JCV LT-Ag in tumor formation in humans. In fact, E. P. Richardson, who first described PML in 1961, reported an incidental case of the detection of an oligodendroglioma in a patient with concomitant occurrence of chronic lymphatic leukemia and PML. Similarly, another case, where a patient with a long history of immunodeficiency syndrome with PML, was described, in which numerous foci of anaplastic astrocytes were observed. Electron microscopy studies revealed the presence of viral particles in the demyelinating lesions in both oligodendrocytes and astrocytes within PML foci, but not in the neoplastic astrocytes. The presence of dysplastic ganglion-like cells in a patient with PML was also recently described, where a large number of dysplastic or dysmorphic ganglion-like cells were detected in the cerebral cortex, which showed properties of neurons. The expression of JCV LT-Ag was detected in those cells but not the viral capsid proteins.

JCV has been shown to be associated with human brain tumors in the absence of PML lesions. The detection of JCV DNA in the brain tumors of an immunocompetent patient with a pleomorphic xanthoastrocytoma was reported. The detection of JCV DNA as well as the expression of LT-Ag in tumor tissue from an immunocompetent HIV-negative patient with oligoastrocytoma was also reported. These two cases demonstrated the association of JCV in brain tumors of immunocompetent non-PML patients. These findings further prompted attempts to establish the association of JCV with different types of brain tumors in humans. Analysis of multiple brain tumors for the detection of JCV genome revealed that 76.9% of astrocytomas, 83.3% of ependymomas, 80% of pilocytic astrocytomas, 62.5% of oligoastrocytomas, 57.1% of oligodendrogliomas and 66% of anaplastic oligodendrogliomas, contained JCV early gene sequence. Furthermore, JCV genomic DNA has also been detected in tumor tissues that originate from non-neural origin. For example, the JCV genome was detected in solid non-neural tumors including colorectal cancers.

Oncogenicity of BKV was also demonstrated in experimental animals including young or newborn mice, rats and hamsters. The route of inoculation mostly determines what types of tumors will be induced by this virus. For example, it is highly oncogenic when inoculated intracerebrally or intravenously, but it weakly induces tumors when inoculated subcutaneously. BKV induces tumors in hamsters in a variety of tumors including neuroblastoma, ependymoma, pineal gland tumors, fibrosarcoma, osteosarcoma, and tumors of pancreatic islets. Rats inoculated with BKV developed osteosarcoma, fibrosarcoma, nephroblastoma, liposarcoma, and glioma. In a similar setting, mice, however, developed only choroids plexus papilloma.

During the late 1970s, detection of BKV DNA in a variety of human tumors and tumor cell lines prompted researchers to further investigate the possible association of BKV with the human tumors. It appears that BKV exhibits a specific oncogenic tropism for the ependymal tissue, endocrine pancreas, and osteosarcomas in rodents. This finding led investigators to primarily focus on the characterization of such tumors in humans for the detection of the BKV genome. Genome detection studies showed that some brain and some pancreatic islet tumors were found to contain the BKV genome in a free, episomal state.

The first detection of the SV40 genome in a metastatic melanoma patient in 1974 linked the association of SV40 with human cancers. The viral genome was isolated from a lung metastasis and the expression of LT-Ag and capsid protein was detected in different organs, including lung, liver and muscle to which metastasis has occurred but not in normal tissue. Since then numerous reports have indicated a possible link between SV40 and human tumors. The SV40 genome and the expression of LT-Ag were detected by different methods, including DNA hybridization, PCR, DNA sequencing and immunofluorescence techniques in mesotheliomas, brain tumors and other human tumors and nontumor tissues including AIDS-related lymphomas, osteosarcomas, peripheral blood cells, kidney tissue from pediatric renal transplant patients and non-Hodgkin's lymphomas.

The mechanism of tumor induction by polyomaviruses is not known, but the tumorigenic protein, LT-Ag, is known to play a major role in this process. This protein was shown to target major cell cycle regulators including retinoblastoma gene products, pRb and tumor suppressor protein p53. This targeting inhibits the functions of these two key cell cycle regulators and perhaps other regulators as well. It should be mentioned here that as opposed to JCV, BKV and SV40 LT-Ag, polyomavirus LT-Ag does not target tumor suppressor p53, suggesting that it has alternative targets in the cell during the cell transformation.

Another mechanism by which human polyomavirus (BKV and JCV) and others including SV40 and mouse polyomavirus LT-Ag may cause cell transformation through the induction of a number of chromosomal structural alterations characterized by the breaks, gaps, dicentric and ring chromosomes, deletions, duplications and translocations. While the molecular mechanism of this clastogenic effect of LT-Ag on host DNA is unknown, it is thought that it may achieve this activity through the interference of the activity of topoisomerase I or through its helicase activity in which it may induce chromosomal damage while unwinding the strands of cellular DNA. This may result in disturbances of the crucial functions of the genes that are important for the maintenance of genomic stability. These important genes may include oncogenes, tumor suppressor genes and DNA repair genes.

In recent years, more direct evidence has been recently presented with respect to the association of a polyomavirus with a specific human tumor type, Merkel cell carcinoma, a rare neuroendocrine skin tumor. H. Feng et al., has first demonstrated the presence of a polyomavirus like sequences in merkel cell carcinoma samples by a digital transcriptome subtraction method. cDNA from the host cell transcripts were subjected to pyrosequencing followed by subtracting out the host sequences from the sequencing data by bioinformatic analysis. Data showed that viral sequences are integrated into the host genome and in some instances either the helicase domain of viral large T antigen or some VP1 sequences are deleted from the viral genome. Later studies showed that expression of large T antigen is required for the maintenance of oncogenic state of the merkel cell carcinoma cells.

Another human polyomavirus associated with a particular human disease is the 'Trichodysplasia Spinulosa' (TS)-associated virus (TSPyV). TSP is a rare skin disease in immunosuppressed patients who manifest papules, spines and alopecia in their facial areas. For the discovery of this virus, samples collected from the specules were subjected to DNA extraction and rolling circle amplification with specific primers followed by DNA sequencing and bioinformatics analysis. Results showed a circular DNA genome similar to that of a polyomavirus. The association of TSPyV with TS disease is now demonstrated to be highly likely.

Papillomaviruses

Classification

Papillomaviruses are composed of a group of small DNA viruses that cause papillomas (warts) in a variety of higher vertebrates, some of which also cause malignant tumors in animals and humans. In particular, human papillomavirus (HPV) genotypes, HPV-16 and HPV-18 induce cervical cancer in women and other epithelial tumors. G. Ciuffo first recognized the viral cause of the human warts more than 93 years ago, through the demonstration of the transmission of common warts using filtrated cell extracts. R. E. Shope first recognized the rabbit papillomavirus in 1933 as the causative agent of cutaneous papillomatosis in cottontail rabbits. Research in the papillomavirus field remained slow over the years because it was not possible to propagate the virus in tissue culture systems until the viral genome was cloned during the late 1970s. This opened up new frontiers in papillomavirus research and cloning of the individual genes of the papillomavirus has provided many opportunities to initiate a systematic mutational analysis of the individual genes out of their context as well as in their background.

Papillomaviruses were initially classified in the papovavirus family along with the polyomaviruses due to the fact that both groups of viruses share common properties, including having a small and double stranded DNA; replicating in the nucleus. They used to be divided into two genera: the papillomavirus and the polyomavirus (mouse polyomavirus and simian virus 40 (SV40)), based on the particles size of each group. That is, papillomavirus is about 53–55 nm and polyomavirus measures about 42–45 nm in diameter size. However, studies of the each group's genome showed that there are fundamental differences between these two viral groups. The papillomavirus genome is about 8 kb and that of polyomavirus is about 5 kb. In addition, the papillomaviruses have more open reading frames for their structural and regulatory proteins than polyomaviruses (compare genomic organization of polyomavirus in Figure 2 with that of papillomavirus in Figure 5). More interestingly, all papillomavirus genes are transcribed from the same strand of the genome, whereas the polyomavirus genome is bidirectional, at least in the case of JCV, BKV, SV40 and mouse polyomavirus. These genomic differences let these two viral groups to be recognized as the distinct virus families.

Figure 5 Circular map of bovine papillomavirus-1 (BPV-1). Approximate locations of the early (E) and late (L) coding regions are depicted. Transcription occurs in the clockwise direction and only one strand of the genome is transcribed. Approximate location of the promoters for early coding regions is indicated as P_n. The promoter for late genes is located between nucleotides 7214 and 7256. The control region is designated as LCR (long control region), which contains the origin of DNA replication (nucleotides 7911–22) and constitutive transcriptional enhancer element (CE). Polyadenylation signal sites for early (A_E, nucleotide 4202) and late (A_L, nucleotide 7175) genes are also depicted.

Figure 6 Expression pattern of human papillomavirus (HPV) in infected epithelial cells. (a) Schematic representation of undifferentiated and differentiated epithelium, containing basal, suprabasal, granular and cornified layers. (b) Different expression levels of HPV genes in undifferentiated and differentiated layers of epithelium are depicted. Expression levels of HPV genes are tightly linked to the differentiation stages of epithelium. E1, E2, E5, E6, and E7 are expressed early during the differentiation. Early gene E4 and late genes (L1 and L2) are expressed during the final stages of differentiation. Viral particles are assembled and released upon cell lysis. The level of viral DNA replication mostly parallels to the early gene expression pattern as depicted.

Papillomaviruses are widespread in nature primarily infecting higher eukaryotes, including humans, cattle, rabbit, horse, dog, sheep, elk, deer, nonhuman primates, harvest mouse and multi-mammate mouse. Some avian species are also infected by the papillomaviruses, including the parrot and chaffinch. This family of viruses displays a highly species-specific infection mode. That is, they do not cause a productive infection in a second species. Most papillomaviruses even present a specific cellular tropism and their life cycle is tightly regulated by the differentiation stages of the epithelial cells that they infect (Figure 6).

To date, more than 150 different human papillomavirus (HPV) types have been completely sequenced. This number is only over 60 for animal papillomaviruses. It is possible that there are still more human and animal papillomavirus types to be discovered. Initially, the genome of HPVs was classified using liquid hybridization techniques under stringent re-association conditions but now classification is based on the nucleotide sequence homologies of specific regions of the genomes. For example, if a newly identified virus has more than 90% sequence homology to the previously identified ones in E6, E7 and L1 open reading frames (ORFs), it is considered to be as a new subtype or a variant, otherwise it is called a new genotype of HPV.

Virion Structure

Like the polyomavirus, the papillomaviruses are small, non-enveloped icosahedral DNA viruses with about 8 kb genome (Figure 5). A virion consists of 72 pentameric capsomers, arranged on a $T=7$ surface lattice. Both the major capsid protein (L1, about 55 kd) representing about 80% of the total viral protein and a minor protein (L2, about 70kd) form the shell of the viral capsid. L1 alone or L1 and L2 together can form virus-like structures (VLPs) in expression systems. L1 plays a major role in infectivity of the virus. The capsomers exist in two states within the capsids; one makes the contacts with six neighbors or the other with five neighbors.

Genome Organization

Genomic organization of all papillomaviruses is remarkably similar. That is, all contain a non-coding region (about 1 kb) and a coding region (Figure 5). The non-coding region is also designated as the viral regulatory region and contains the origin of DNA replication and the promoter/enhancer elements that serve as binding sites for many transcription factors. One of the remarkable characteristics of all papillomavirus genomes is the fact that only one of the strands of the genome serves as template for transcription. A typical papillomavirus genome contains 10 open reading frames (ORFs), some of which encode regulatory proteins and some structural (capsid) proteins. The degree of the expression levels of an ORF is dependent upon the differentiation state of the infected cells. That is, the early region of the viral genome is mostly expressed during initial stages of infection cycle and during the non-productive infection cycle of the virus. This region encodes only regulatory proteins, including those that are necessary for initiation of viral DNA replication and maintenance of the viral genome in infected cells. The late ORFs, however, encode viral structural proteins and are expressed only in productively infected cells (Figure 6).

Life Cycle

Papillomaviruses have a remarkable life cycle. The expression levels of ORFs of the viral genome are tightly regulated by differentiation states of the infected squamous epithelial cells. In other words, the infection stages (early and late) are tightly linked to the differentiation stage of the epithelial cells (Figure 6). The productive infection cycle of the virus can be divided into early and late stages. Initial infection takes place at the basal epithelial cells, which are the only cells in the squamous epithelium that are capable of dividing (Figure 6). The infection cycle starts with the attachment of the viral capsids to the cell surface receptors. $\alpha 6$ -integrin plays an important role in this process, although it is not an authentic receptor for viral entry. The heterodimeric forms ($\alpha 6\beta 4$ or $\alpha 6\beta 1$) of the integrins appear to serve better binding sites for viral attachment than individual ones and are also good candidates for being a receptor for papillomavirus entry. The virus also enters the cells in the absence of these molecules, suggesting that this complex is not 100% necessary for viral entry. Papillomaviruses can also bind to heparin, cell surface glycosaminoglycans on human keratinocytes, which suggests that they may also play a supportive role in viral entry. Attachment of the virus is followed by internalization as shown in polyomavirus case, in Figure 3, and by the transport of the virus to the nucleus. It is not known where the uncoating process takes place. However, it is likely that, as is the case for polyomaviruses at least in the case of SV40, papillomaviruses may use the protein folding machinery in the endoplasmic reticulum (ER) for the initial uncoating of the viral particles. The treatment of infected cells with cytochalasin B and paclitaxel (Taxol) inhibits transport of the virions, suggesting that microtubules and microfilaments play a role in viral transport.

Transcription and replication of papillomaviruses are very complex processes. The virus uses multiple promoters and alternative splice patterns in different cells during the transcription and splicing processes, suggesting that the virus has the ability to adapt itself to different cell environments for its productive cycle. The differential promoter usage of the virus appears to result from the support of cell-type specific transcription factors. In other words, cell-type specific transcription factors make the expression of different viral promoters and splice patterns possible. This could be one of the explanations why papillomavirus requires differentiated patterns of the epithelial cells during its life cycle. The expression of the viral genome is tightly regulated and is dependent on the differentiation process of the epithelial layers (Figure 6). The virus infects the basal cells of the epithelium and the low level of viral early protein expression (E6 and E7) and that of viral DNA replication occurs in these cells. Then, the virus infects the subbasal cells, where, in addition to E6 and E7, E1, E2, E4 and E5 proteins are continuously produced. The viral genome is also amplified at relatively high levels in these cells. Vegetative replication of the viral genome takes place at the terminally differentiated epithelial cells, where the viral capsid proteins, L1 and L2, are expressed, virions are assembled, and finally the infected cells are lysed (Figure 6).

Viral Proteins

The papillomavirus genome as mentioned previously encodes regulatory and structural proteins. Early protein-1 (E1) is a regulatory protein and required for the replication and maintenance of the viral genome. E2, a major transcriptional regulator of the viral genome, is involved in viral DNA replication and transcription. It activates viral genome through interaction of the E2-responsive elements located with the viral regulatory region. E2 protein is relatively conserved among the papillomaviruses and contains two major domains; sequence-specific DNA binding domain and dimerization domain, which is located in the carboxyl-terminal domain of the protein. It also contains a transactivation domain, located towards the amino-terminal half of the protein. Mutations within the E2 coding region have deleterious effects on viral transcription, replication and virus-induced transformations, namely those event are disrupted. The function of E4 protein is not clear, although it has the ability to disrupt the cytokeratin networks. It is also involved in the splicing of viral transcripts. It is an early protein but is expressed during the late vegetative state of the viral infection cycle, suggesting that it may play a role in viral encapsidation process. E5 protein is another regulatory protein, and is indirectly involved in the promotion of cell growth, because it activates the epidermal growth factor receptor in infected cells. It has also the ability to inhibit the expression of one of the cell cycle inhibitors, p21, through which it may also affect the cell cycle control. HPV encodes two major oncoproteins, E6 and E7. They are also involved in maintenance of the viral genome in an episomal state, during the productive infection cycle. E7 has been suggested to play a role in disruption of keratinocyte differentiation process. L1 and L2 are the major and minor capsid proteins of the papillomavirus respectively.

Transforming Ability of Papillomaviruses and Their Oncoproteins

Although bovine papillomavirus-1 (BPV-1) has been intensively used to investigate the transforming ability of papillomaviruses in tissue culture, due to their clinical importance, we focus our efforts on the oncogenic properties of human papillomaviruses (HPVs). High-risk HPVs, HPV-16 and HPV-18, are capable of transforming primary rodent cells, primary human fibroblasts and keratinocytes, but low-risk HPVs, HPV-6 and HPV-11 are not able to do so. HPV-16 and HPV-18 alone do not transform primary rat fibroblasts, however, E7 protein of those viruses can do so by cooperating with activated ras gene.

HPV E5 protein

E5 oncoprotein is highly conserved among the papillomaviruses that display an oncogenic property. It shows a growth stimulatory effect on cells and localizes to the golgi apparatus, endosomes and to some extent to the cell membranes. It is associated with the activation of the epidermal growth factor (EGF) receptor and mitogen activated protein (MAP) kinase pathways. It binds to a 16 kd

subunit of the vacuolar ATPase and can inhibit the acidification of endosomes. A controversy surrounding its nature is that it is not expressed in most HPV-positive cancer cells, suggesting that if the E5 gene is involved in cell proliferation, it presumably functions in benign papillomas and not in the cancers. It may also be involved in the initial stages of the cell transformation rather than later stages. This would be another explanation for not being expressed in cancer cells and yet has the ability to induce growth stimulatory pathways.

HPV E6 oncoprotein

E6 oncoprotein provides a helper function to E7 to transform cells and is a more potent protein with respect to cellular transformation. For example, E7 is sufficient for the transformation of established rodent cells such as NIH 3T3 but the combination of E6 and E7 can readily extend the life span of human keratinocytes and can lead to the outgrowth of immortalized clones. It is a 150 amino acid long protein with four C-X-X-C motifs, which are believed to bind to Zinc.

All oncoproteins evolved mechanisms to disrupt the normal cell cycle regulation, through targeting of the cell cycle regulators including p53, a tumor suppressor protein that is activated in response to the DNA damage and genotoxic stress. It mediates the arrest of the cells at the G1 phase of the cell cycle until DNA damage is repaired. If the damage is unreparable, it induces apoptotic pathways to eliminate the damaged cells. It causes the G1 arrest by inducing the p21 cyclin-dependent kinase inhibitor encoded by the WAF1 gene. Like the SV40 LT-Ag and the Ade5E1B 55 kd protein, the E6 oncoprotein of HPV can complex with p53. However, unlike SV40 LT-Ag and Ade5 E1B 55 kd protein, the interaction of E6 with p53 leads to the degradation of the protein rather than stabilization of it. In both cases, in practical terms, the function of p53 is greatly impaired, which leads to genomic instability and finally to cell transformation.

E6 can also have p53-independent functions with respect to cell transformation. For example, a mutant of E6 oncoprotein cannot bind p53 but can promote colony formation on soft agar, suggesting a p53-independent function of E6 oncoprotein during cell transformation. E6 can also induce telomerase activity when expressed in the cell, through which it may contribute to cell transformation by a p53-independent pathway(s). Telomerases are known to be highly active in transformed cells. In addition, E6 targets the cellular proteins like those that are involved in negative growth regulation and mediates their degradation by ubiquitination, through which it may also contribute to the cell transformation. One such target of E6 is the PD2-domain containing proteins.

HPV E7 oncoprotein

E7 is another regulatory protein of papillomaviruses. It is a small nuclear protein of 100 amino acids. It shows functional similarity to Ad 12S E1A protein in that it activates the Ad E2 promoter, induces DNA replication in quiescent cells and cooperates with an activated ras oncogene for transformation of rodent cells. It appears that the functional similarity between these two proteins stems from the fact that it shares important amino acid sequence similarity with the portions of Ad E1A protein (Figure 7) and SV40 LT-Ag. Those shared sequences are important for their function with respect to targeting cellular regulatory proteins, including retinoblastoma protein, pRb and pRb-related proteins, p107 and p130. pRb family of proteins are a group of regulatory proteins critically involved in the G/S phase transition. They are active in their dephosphorylated state, targeting the S phase-specific transcription factors, namely the E2F family of proteins. In other words, they tightly bind to the E2F family of proteins in their dephosphorylated state and prevent their transcriptional activity, through which they arrest the cells at the G1 state of the cell cycle. Upon hyperphosphorylation by the cyclin-dependent kinase complexes, the pRb family of proteins releases E2F and subsequently free E2F binds to the promoter regions of S phase-specific genes and activates their transcription. Finally, cells enter S phase for DNA replication. As is

Figure 7 Schematic structure of HPV E7 oncoprotein. HPV E7 and Ad5 E1A proteins show sequence similarity between portions of conserved region 1 (CR1) and conserved region 2 (CR2). CR2 of HPV contains the casein kinase II phosphorylation site and the pRb binding site. The approximate location of the pRb binding domain, pRb degradation domain and Zn binding domain are also depicted.

case for the targeting and degradation of p53 by HPV E6 oncoprotein, E7 protein binds to pRb and induces its degradation, through which it largely contributes cell transformation. However, genetic studies showed that the targeting of the pocket proteins by E7 oncoprotein is not sufficient to account for its immortalization and transformation functions. This suggests that E7 appears to have additional cellular targets that are involved in E7-mediated cell transformation. Such targets may include TATA binding protein (TBP), activating protein-1 (AP-1), F actin and Forkhead transcription factor, but the physiological relevance of this targeting by E7 is not clear.

E7 oncoprotein also targets other regulatory proteins, involved in cell cycle regulation, including cell cycle-dependent kinase inhibitors, p27 and p21. p27 is involved in mediating cellular growth inhibition by transforming growth factor β (TGF- β) in keratinocytes. This activity of E7 may also contribute to the transforming activity of E7 in that E7 may override indirectly TGF- β associated growth arrest and eventually have a positive effect on cell transformation. p21 is a cyclin-dependent kinase inhibitor and inhibits the kinase activity of cdk4/cyclin E complex. E7 inhibits the inhibitory function of p21 and thereby contributes to the unscheduled S phase entry and cell cycle progression. The E7 oncogene appears also to induce abnormal centrosome duplication, the mechanism of which is unknown. Such an abnormality is known to lead to genomic instability, which is one of the processes that is very often encountered in cancer cells. Such an activity of E7 is therefore possibly functionally relevant to the HPV-mediated cell transformation.

Glossary

Capsular polysaccharide (CPS) An exocellular polysaccharide secreted in such a large amount that it encapsulates a microorganism, facilitating adhesion and helping screen from immune response. Sometimes a distinction is made with more loosely attached polysaccharides 'released polysaccharide' (RPS).

Epimerase An enzyme that converts mannuronic acid residues to guluronic acid residues in alginates.

Intrinsic viscosity, $[\eta]$ (mL g^{-1}) A measure of a particle's conformation and volume occupancy in solution.

Mark-Houwink 'a' parameter A measure of the conformation of a macromolecule, and determined from measurements of solution viscosity and molecular weight. Limits are 0 (sphere), 1.8 (rod), with values 0.5–0.8 for a flexible coil-like molecule.

Molecular weight (Da or g mol^{-1}) Popular terminology for 'molar mass' – the mass of 1 mol (6.023×10^{23}) molecules.

Molecular weight – number average, M_n (Da or g mol^{-1}) In a mixture of macromolecules M_n is the molecular weight averaged over the number concentrations of each species. It can be determined by techniques such as osmotic pressure, size exclusion chromatography coupled to multiangle light scattering (SEC-MALLs) or analytical ultracentrifugation.

Molecular weight – weight average, M_w (Da or g mol^{-1}) In a mixture of macromolecules M_w is the molecular weight averaged over the weight concentrations of each species. It can be determined by techniques such as size exclusion chromatography coupled to multiangle light scattering (SEC-MALLs) or analytical ultracentrifugation.

Non-Newtonian fluid A fluid in which viscosity changes with applied strain, an example of which is shear thinning.

Persistence length, L_p (nm) A measure of the flexibility of a linear macromolecule ranging from ~ 2 nm for a very flexible molecule to ~ 200 nm for very stiff.

Polydispersity index The ratio of the weight average molecular weight to the number average molecular weight, M_w/M_n . Minimum value=1.

Nomenclature

CPS	capsular polysaccharide
GDP	guanosine diphosphate
GRAS	generally regarded as safe
HA	hyaluronic acid
RPS	released polysaccharide

Defining Statement

Microbial polysaccharides are used for food, pharmaceutical, and medical applications: this wide range of usefulness derives from the great diversity in structural and functional properties. We consider the structure, properties, extraction, production, modification, and applications of commercially available microbial polysaccharides including xanthan, xylinan, gellan, curdlan, pullulan, dextran, scleroglucan, schizophyllan, and cyanobacterial polysaccharides.

Introduction

Over the last two decades there has been an expanding interest in polysaccharides produced extracellularly by microorganisms for food, pharmaceutical, and medical use, including vaccines. The wide range of their usefulness derives from the great diversity in structural and functional properties even though they are built up from very similar building blocks: the pyranose or furanose carbohydrate ring structure. One can have rod-shaped molecules like schizophyllan and scleroglucan from the fungi *Schizophyllum commune* and *Sclerotium rolfsii*, respectively, linear random coil type structures like pullulan from the fungus *Aureobasidium pullulans*, and intermediate structures such as alginates from the bacterium *Azotobacter vinelandii*. One can have highly electronegative or

[☆]*Change History:* December 2016. Shi Lei and Tian Feng Edmund added new references; updated throughout the text, revised all figures and introduced new ones.

This article is an update of G. Morris, S. Harding, Polysaccharides, Microbial, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 482–494.

'polyanionic' molecules like xanthan secreted by *Xanthomonas campestris* or neutral polysaccharides like dextrans from the bacteria *Leuconostoc mesenteroides*.

Polysaccharides made by microorganisms are secreted from the cell to form a layer over the surface of the organism, often of substantial depth in comparison with the cell dimensions (Fig. 1). Because of their position they are characterized as exopolysaccharides, to distinguish them from any polysaccharides that might be found within the cell. The functions are thought to be mainly protective, either as a general physical barrier preventing access of harmful substances, or more specific as a way of binding and neutralizing bacteriophage. In appropriate environments they may prevent dehydration.

They may also prevent phagocytosis by other microorganisms or the cells of the immune system. The capsular polysaccharides (CPSs) are often highly immunogenic, and may have evolved their unusual diversity as a way of avoiding antibody responses: advantage of this feature can be taken in the development of vaccines. They also have a role in adhesion and penetration of the host. In the case of plants this involves interaction with polysaccharide structures in the cell walls and there are possibilities of specific interactions. Plant lectins (glycoproteins) that have specific binding properties with respect to carbohydrate structures may play a part in this and in the general defense of plants against bacterial infection.

Some secreted polysaccharides can be involved in pathogenicity. *Pseudomonas aeruginosa*, commonly found in respiratory tract infections, produces alginate which contributes to blockage in the respiratory tract, and leads to further infection, and similar blockages of phloem in plants have also been described. However, the secreted polysaccharides themselves present virtually no known toxicity problems and many are harvestable at low cost in large quantities, making them attractive for biotechnological use.

Microbial products are very important in all aspects of polysaccharide biotechnology. They range from bulk materials such as xanthan, priced at about US\$10 per kg, used mainly in food and personal care consumption and oil industry, to cyclic dextrans, valued at about US\$30 per kg and used in high-value applications in research and pharmaceuticals.

Certain microbes are known to produce nearly all the major plant polysaccharides such as glucans, alginate-like materials, and even cellulose – as well as the complex bacteria-specific materials. Genetic manipulation of bacteria has been studied for longer and is in general much easier than for higher organisms, so that they are an obvious target for both manipulation of biosynthetic pathways and the expression of heterologous genes to produce especially desirable enzymes. Polysaccharides are not of course under the direct control of genetic material in the way that enzymes are, and must be approached indirectly by manipulating the biosynthetic or degradation pathways by way of the enzymes responsible: there is currently great scope for this approach. In addition, since there are now fermentation processes involving the large-scale growth of bacteria, all the advances in this field can be achieved by biotechnology.

There are also limitations. It is unlikely that large-scale fermentation could ever compete with existing processes for pectin manufacture, for example, since processors currently use waste by-products from other processes as their raw material. This is quite apart from the inherent costs of large-scale fermenters in comparison with simple extraction processes. It follows that bacterial products must have particularly useful properties in order to justify their probable greater cost.

Ultrastructural localization of capsules, cell wall polysaccharide, cell wall proteins and F antigen in pneumococci. *Infection and Immunity* 56, 1890–1896. Reproduced with permission from the American Society for Microbiology.

This article looks at the production, properties, and biomodifications where appropriate of a selected range of important microbial polysaccharides because it is impossible to cover each substance comprehensively. Instead, we focus on xanthan as our main example because of its commercial importance but also consider xanthan-like exopolysaccharides such as gellan, XM6, curdlan, xylinan, and the increasingly important group of cyanobacterial polysaccharides – also xanthan-like – as well as pullulan, dextrans, scleroglucan, schizophyllan, microbial hyaluronic acid (HA), and bacterial alginates as representative examples. We complete our review with a look at the use and potential further use of exopolysaccharides as vaccines against serious diseases such as meningitis in infants.

Xanthan

Structure

Xanthan (or, as commonly called, xanthan gum) at US\$10 per kg falls in a similar price range as other gums and exudates and has similar functional properties. It is made by the organism *Xanthomonas campestris*, strain NRRL B-1459 (which in its existence in the wild is responsible for cabbage blight) grown largely on glucose, itself derived from maize starch, which it converts with high efficiency (80%) to the xanthan gum structure. Typically, for a fermentation product, the raw material costs are a small part of the total, which are mainly to do with recovering the gum from the culture medium. Worldwide consumption of xanthan in 2014 was estimated between 150,000 and 160,000 metric tons, produced by companies in Europe (Jungbunzlauer), China (Deosen, Fufeng, Jianlong, Meihua), and United States (CPKelco, ADM, Cargill, DuPont/Danisco)). It has a $\beta(1\rightarrow4)$ -linked glucan main chain with alternating residues substituted on the 3-position with a trisaccharide chain containing two mannose and one glucuronic acid residue (Fig. 2). It is thus a charged polymer. Some of the mannose residues may also carry acetyl groups. It is useful because it forms relatively rigid rod-like structures in solution at ambient temperatures, though they convert to the random configuration on heating. These rods are able to align themselves, rather like agarose and the κ - and ι -carrageenans, with the unsubstituted regions of galactomannans, such as guar and its derivatives and locust bean gum, to produce fairly rigid mixed gels with applications in food manufacture.

The primary structure (as worked out by sequential degradation and methylation analysis) consists of a repeating unit of β -D-glucose:

and in this respect it resembles cellulose, with the important difference that with the substitution at C3 (i.e., the third position on the carbon ring) every alternate Glcp residue is substituted by a negatively charged trisaccharide involving mannose and acetylated mannose:

with some of the terminal β -D-Manp residues substituted at positions C4 and C6 by pyruvate $CH_3.CO.COO^-$. Thus xanthan (except under highly acidic conditions) is, like alginate, a highly charged polyanion. Fig. 2(a) shows the Haworth projection of a (pyruvalated) alternate repeat section of xanthan.

It is not only charge repulsion effects that convey on xanthan an extended rigid rod conformation. X-ray fiber diffraction studies have shown the presence of some helical structure although there is still uncertainty as to whether this helix is a coaxial duplex or just a single chain one, with the projecting trisaccharides folded back along the axis of the helix giving a chain rigidity effectively similar to that of a double helix. Using a combination of electron microscopy (contour chain length, L), and light scattering (weight average molecular weight, M_w), Stokke and coworkers evaluated a mass per unit length, M_L , of 1950 ± 250 g mol^{-1} nm $^{-1}$. From X-ray fiber diffraction studies, a corresponding value of 950 g mol^{-1} nm $^{-1}$ was obtained, and a duplex or double-helical structure was inferred for the native structure. High temperatures reversibly melt this helix to give a more random structure.

Production Process

The primary laboratory and commercial fermentation medium – as has been known for over 50 years – for *X. campestris* growth and xanthan production is a phosphate-buffered (pH ~ 7) broth containing D-glucose (30 g L $^{-1}$) (or sucrose, starch, hydrolyzed starch), NH_4Cl , $MgSO_4$, trace salts with 5 g L $^{-1}$ casein (or soybean) hydrolysate, and the fermentation process takes place aerobically at a temperature of $\sim 28^\circ C$. Xanthan production is further stimulated by the presence of pyruvic, succinic, or other organic acids. The xanthan produced in this way is very similar to the naturally produced xanthan made by the microbes living on a cabbage. In the commercial process the oxygen uptake from the broth is controlled to a rate of 1 mmol L $^{-1}$ min $^{-1}$. Treated in this way the bacterium is an extremely efficient enzyme minifactory converting $>70\%$ of the substrate (D-glucose or related) to polymeric xanthan. Following precipitation, xanthan fibers are separated by filtration or centrifugation, dried, milled, and packed (Fig. 3). Used isopropanol, which is collected from the solid-liquid separation step and from the drying process, is distilled in a rectification column and reused. Xanthan production is an energy-intensive process, especially power for the agitation of the fermenters, cooling, and rectification contribute to a great extent to variable production costs.

Fig. 2 (a) Pentasaccharide repeating unit of xanthan and binding sites for cations (M^+). (b) Xylinan (acetan) repeat unit showing a pentasaccharide side chain.

The biosynthetic process by the bacterium worked out by Sutherland and later confirmed by others follows the same basic pattern proposed for other microbial polysaccharides: (1) substrate uptake; (2) substrate metabolism; (3) polymerization (4) modification and extrusion, and involves lipid carriers (although there is still uncertainty over their precise role and how the whole process is controlled).

Xanthan biosynthesis is an energy intensive process with a high number of enzymes which are either directly or indirectly involved in the synthesis. Glucose is mainly metabolized via the Entner-Doudoroff pathway and the citric acid cycle to build up biomass and produce energy rich intermediates. Fig. 4 shows a model for the synthesis of xanthan in *X. campestris*. It is assumed that the first steps are the assembly of the pentasaccharide unit which are subsequently polymerized and exported. The genes which are directly involved in the xanthan synthesis are located on the gum-operon, a cluster of 12 genes, named *gumB*, *gumC* to *gumM*.

Fig. 3 Industrial production process of xanthan.

Fig. 4 A model for the synthesis of xanthan at the cell membrane of *X. campestris* (reproduced with permission from Vorhölter F.-J., *et al.*, 2008. Journal of Biotechnology 134, 33–45). The letters in the green fields represent the enzymes involved in xanthan production.

Properties

These molecules are extremely large, for example, the weight average M_w of keltrol xanthan has been found by ultracentrifuge techniques to be $\sim 6 \times 10^6 \text{ g mol}^{-1}$, and stiff, with a molecular persistence length L_p of $\sim 150 \text{ nm}$ (the practical limits for linear molecules are $\sim 2 \text{ nm}$ for a very flexible, or 'random coil' structure, and $\sim 200 \text{ nm}$ for a rigid rod structure). Xanthan gives very viscous solutions (intrinsic viscosities, $[\eta]$, approximately several thousand milliliters per gram) and indeed is one of the largest of the aqueous soluble polysaccharides. The very high viscosity at low concentrations (e.g., at 5 mg mL^{-1} a viscosity of $\sim 1000 \text{ cP}$ has been observed at room temperature) makes it ideal as a thickening and suspending agent.

Xanthan is a tasteless, white to cream-colored free-flowing powder soluble in hot and cold water, but insoluble in most organic solvents. Besides the above described high viscosity at low concentrations, xanthan still has many valuable properties compared to

other hydrocolloids: 1) highly pseudoplastic over a broad shear range; 2) good thermal stability; 3) good stability over a broad pH spectrum; 4) resistant to degradation by most enzymes; 5) soluble and stable in salt solutions; 6) synergistic behavior with galactomannans.

It is these unique physicochemical properties that make xanthan be widely used in food, animal feed, personal care, pharmaceutical, and industrial fields. For example, the industrial importance of xanthan is based on its ability to control the rheology of water based systems.

Modification

Modifications of xanthan usually occur at three different stages of the production process: 1) modifications at the molecular structure; 2) modifications during downstream processing; 3) end-product modifications. The most common modifications at the structure of xanthan are variations of the acetate or pyruvate content.

The key sites for modification are the first and terminal mannose residues on the trisaccharide side chains (particularly extent of acetylation of the first and pyruvalation of the latter) and the helical backbone formed by noncovalent interactions with galactomannans: these interactions also appear to be affected by the substitutions in the side chains. Insofar as the trisaccharide side chains are concerned there are two approaches for alteration or control: one is changing the physiological conditions of fermentation; the other is the use of different pathovars or strains of *X. campestris*. The pathovars *pv phaseoli* and *oryzae* yield virtually acetyl-free and pyruvate-free xanthan, respectively.

The other approach has been to look at the genetics of the enzymes controlling the biosynthetic pathway and to attempt to produce and isolate in sufficient quantity genetic mutants deficient or defective in one or more of these enzymes to give 'polytetramer' (i.e., lacking in the terminal mannosyl or pyruvalated mannose group) and 'polytrimer' (lacking in addition the adjacent glucuronic acid residue). Although yields of 50% polytetramer have been found, corresponding attempts for polytrimer and other xanthan variants have thus far been disappointing.

There has been considerable interest in improving the weak gelation characteristics of xanthan by inclusion of galactomannans such as locust bean gum and gum into mixtures. As with carrageenan and agarose, excellent synergistic interaction occurs between xanthan and the galactomannans such as locust bean gum or guar. Xanthan gels are very weak and transient but made in the presence of guar or locust bean gum give stronger gels with an optimum mixing ratio ~50:50 by weight. Deacetylating the xanthan side chains seems to enhance these synergistic interactions.

Uses of Xanthan

Xanthan was approved as food grade by the US Food and Drug Administration nearly 30 years ago. This makes it not only attractive as a food product but also useful in packaging material in contact with food and also for use in pharmaceutical and biomedical applications that involve ingestion. Its uses chiefly derive from its solubility in hot and cold water and its very high thickening and suspending potential, which in turn derives from the very high viscosity of its suspensions. Despite its high viscosity, xanthan suspensions exhibit high shear thinning, which means they also flow easily (i.e., good pourability). For food applications, xanthan suspensions have high acid stability besides high viscosity and thickening and suspending ability. This makes it highly popular in sauces, syrups and toppings, and salad dressings. In drinks, the addition of xanthan together with carboxymethylcellulose adds body to the liquid and assists with uniform distribution of fruit pulp. It is also used to add body to dairy products. The high freeze-thaw stability of xanthan suspensions makes it particularly attractive for the frozen food industry. The high suspending and stabilizing properties are also taken advantage of by the animal feed industry for transporting liquid feeds with added vitamins and other supplements, which would otherwise sediment out during transport or with storage time. It has also been suggested as an additive to fruit drinks to reduce tooth decay. For pharmaceuticals, xanthan has recently been added to the list of hydrophilic matrix carriers, along with chitosan, cellulose ethers, modified starches, and scleroglucan. Tablets containing 5% xanthan gum under low shear conditions were shown to enable the successfully controlled release of acetaminophen into stomach fluid and tablets containing 20% xanthan successfully carried a high loading (50%) of the drug theophylline. The high suspension stability is made use of in pharmaceutical cream formulations and in barium sulfate preparations. This high cream stability is also taken advantage of by the cosmetic industry, including toothpaste technology, facilitating the suspension of ingredients (high viscosity) and the easy brushing onto and off the teeth (high shear thinning). Uniform pigment dispersal along with other ingredients and long-time stability make xanthan a good base for shampoos. The high suspension stability of xanthan makes it an ideal base for suspending adhesive agents for wallpapers. Just to reinforce the diversity of application, the suspension-stabilizing property of xanthans makes it ideal for producing sharp prints from dyes, with a minimum risk of running in textiles and (in conjunction with guar) carpets.

In summary, due to its extraordinary properties as stabilizer and thickener, xanthan is extensively used in the food, personal care and pharmaceutical industry. In addition, xanthan is applied in various industrial applications and for oil drilling. In all of these areas xanthan is recognized as an excellent stabilizer and useful processing aid. Table 1 lists the functions of xanthan in various applications.

Table 1 Some examples of xanthan applications

Application	Usage in (%)	Function
Food		
Salad dressings	0.1–0.5	Provides easy pourability and good cling; suspends spices
Bakery products, gluten free bakery	0.05–0.3	Binds water; improves texture and moisture retention; suspends fruits and nuts
Beverages	0.05–0.2	Enhances mouthfeel; suspends fruit pulp
Instant products	0.05–0.2	Contributes body; quick viscosity build up in cold and hot water
Prepared food	0.1–0.3	Stabilizes; avoids syneresis
Soups, sauces and gravies	0.05–0.5	Provides good temperature stability; prevents separation; improves texture
Frozen food	0.05–0.2	Provides good freeze/thaw stability; contributes smooth texture
Dairy products	0.05–0.2	Inhibits syneresis; stabilizes emulsions
Toppings	0.05–0.3	Stabilizes foams and emulsions; provides good flow and cling
Meat products	0.2–0.5	Binds water; inhibits syneresis
Low-calorie products	0.1–0.5	Improves texture; stabilizes
Personal care		
Toothpaste	0.7–1.0	Provides easy pumpability and excellent flow properties; gives good stand on the brush

Tablets	1.0–3.0	Retards drug release
Lozenges	0.3–1.0	Prolongs contact time of active ingredients

Xylinan (Acetan)

Structure

Xylinan (or acetan) is a complex anionic exopolysaccharide produced by the Gram-negative bacterium *Acetobacter xylinum*. The structural repeat unit is similar to that of xanthan and consists of a cellulosic backbone ($\dots \rightarrow 4) \beta\text{-D-Glcp}(1 \rightarrow \dots)$ where alternate glucopyranose residues are substituted at the 3-position with a pentasaccharide side chain (Fig. 2(b)):

The branched glucopyranose residues together with the mannopyranose residue are partially O-acetylated at the 6-position. The pentasaccharide side chain protects the cellulosic backbone from enzymatic degradation by cellulases.

Analysis from X-ray diffraction and atomic force microscopy show that xylinan adopts a helical structure in both the solid and solution phases. Hydrodynamic characterization using sedimentation velocity in the analytical ultracentrifuge, viscometry, and multiangle laser light scattering (MALLs) have shown that double-stranded helices are predominant although single- and multi-stranded chains are also present. Xylinan chains upon heating undergo thermoreversible helix (ordered state)–coil (disordered state) transition.

Extraction and Production

Xylinan is extracted as a water-soluble by-product during the commercial production of bacterial cellulose by *A. xylinum*.

Properties

These molecules are extremely large and a weight average M_w of $\sim 2.5 \times 10^6 \text{ g mol}^{-1}$ has been found by ultracentrifuge and light scattering techniques. Furthermore, the double-helical structure results in a stiff macromolecular chain with a molecular persistence length L_p of $\sim 100 \text{ nm}$ and a mass per unit length M_L of $\sim 2500 \text{ g mol}^{-1} \text{ nm}^{-1}$, resulting in viscous solutions, $[\eta]$, approximately several thousand milliliter per gram. A Mark-Houwink 'a' parameter of 0.90 was found, which is consistent with a rigid conformation. Intermolecular binding has been demonstrated between xylinan and the industrially important glucomannan (konjac gum) and galactomannan (carob gum), resulting in the formation of synergistic gels (or increased viscosity at lower concentrations).

Modification

Chemical modification of xylinan has been through deacetylation of the 6-linked O-acetyl groups. It has been shown that acetylation does not prevent helix formation but it does reduce the synergistic interaction with glucomannans or galactomannans.

Xylinan synthesis involves several genes including *aceA*, *aceB*, *aceC* and it has recently been shown that chemical mutagenesis of the native bacterium results in a strain that produces a polysaccharide in which the side chain is a tetrasaccharide. Furthermore, this novel xylinan variant has higher viscosity. A further novel polysaccharide with a trisaccharide side chain was designed by deactivating the *aceP* gene.

Uses

Xylinan is used in the food industry as a viscosifier and gelling agent. It is also a component in nata, a confectionery popular in Japan and the Philippines.

Gellan, XM6, and Curdlan

Inspired by the example of xanthan, other bacterial polysaccharides with useful properties have been developed, for example, gellan, the result of a systematic search for a polysaccharide having the required properties, followed by the identification of the organism.

Gellan is obtained from cultures of *Pseudomonas elodea* found growing on the elodea plant. It is isolated by ethanol precipitation from the culture medium, and may be partially deacetylated by alkali treatment. It has a linear structure with a repeat unit of a tetrasaccharide (Fig. 5), each with one carboxyl group and in the native state one acetyl group. It is therefore sensitive to calcium levels but has some rheological properties similar to those of xanthan, which has a similar charge density and adopts a double-helical conformation in solution. The double-helix molecular weight is reported to be $\sim 5 \times 10^6$, with an intrinsic viscosity of $\sim 3500 \text{ mL g}^{-1}$.

It was clearly intended to be a xanthan competitor, though before permission for food use was obtained it was promoted as an agar substitute, particularly for use in growth media. Gels produced on untreated gellans are weak and rubbery although deacetylation produces hard, brittle gels, and after prior removal of all multivalent cations and addition of Ca^{2+} ions, gellan forms gels in rather the same way as with alginates. It is one of many film-forming polysaccharides being considered for use in implants for insulin in the treatment of diabetes.

The XM6 repeat unit structure is also shown in Fig. 5 and is a polysaccharide made by an *Enterobacter* discovered at Edinburgh University. It lacks acetyl groups but is classed along with xanthan and gellan, and can be induced to gel by adding calcium ions. It is included here as a representative of many similar bacterial polysaccharides all of which have interesting and potentially useful rheological properties, although it is not commercially available, and as far as we are aware has not been approved for food use, and probably never will.

Curdlan is one of two polysaccharides produced by *Alcaligenes faecalis* with a repeat unit of three $\beta(1 \rightarrow 3)$ -linked D-glucose residues and unlike the examples above is not charged. Curdlan suspensions gel on heating, apparently irreversibly. There are a number of potential applications for it in the food industry, mostly as a replacer for existing gums, and it is in use in Japan in some products. Novel products based on its heat set ability may also appear.

Cyanobacterial Polysaccharides

Another group of polysaccharides with reputed xanthan-like properties are the exopolysaccharides from Cyanobacteria – blue-green algae – known to produce large amounts of these substances.

Fig. 5 Repeat units, gellan in deacetylated form (a), the XM6 polysaccharide (b), and curdlan (c).

Structure

Like xanthan, the cyanobacterial polysaccharides are relatively complex containing on average 6–10 different saccharide residues, with the neutral sugars xylose, arabinose, fucose, galactose, rhamnose, mannose, glucose, and uronic acids, with glucose normally being the dominant residue. Charged groups such as sulfate and pyruvate together with hydrophobic groups, for example, acetates have also been reported. All the cyanobacterial polysaccharides studied so far have been branched structures.

Extraction and Production

Due to their diversity, cyanobacteria are found growing under a wide variety of conditions. Nitrogen seems to have a negative effect on polysaccharide production whereas temperature, salinity, illumination, and exposure to UV radiation can have either positive or negative effects on exopolysaccharide production in cyanobacteria. It is worth noting that optimal exopolysaccharide production does not necessarily coincide with those for cell growth. The daily production of cyanobacterial polysaccharides from different sources is up to 2 g L⁻¹, which is small in comparison to xanthan production, which can be up to 10 g L⁻¹. The general process of extraction, production and characterization of microalgal and cyanobacterial exopolysaccharides is shown in Fig. 6.

Properties

Cyanobacterial exopolysaccharides have been shown (Fig. 7) to exhibit xanthan-like shear-thinning properties. Polysaccharide molecular weights have been measured in the range of 1–2 × 10⁶ g mol⁻¹ and 'gross' macromolecular conformations have been estimated to be a random coil for the exopolysaccharide from *Cyanospira capsulata* (CC-EPS), a rigid rod type polysaccharide from *Aphanotheca halophytica* GR02 (AH-EPS), or intermediate between random coil and rigid rod for the polysaccharide from *Anabaena* sp. ATCC 33047.

Uses

The importance of cyanobacterial polysaccharides of biological soil crusts (BSCs) in sand surface stabilization and soil nutrient retention has been long acknowledged. These exopolysaccharides are of potential biotechnological importance as conditioners of

soils as they improve water-holding capacity; as emulsifiers, viscosifiers, medicines, biofloculants; and for heavy metal removal. A pectin-like polysaccharide that is able to absorb metal cations has also been described.

Pullulan

Pullulan is an α -glucan made up from maltotriose units linked by $\alpha(1\rightarrow6)$ bonds (Fig. 8). It is obtained from *Aureobasidium pullulans* and is hydrolyzed by pullulanase to yield maltotriose. It is not attacked by digestive enzymes of the human gut, and is used to form films. Production is now substantial, and has found particular application in formulating snack foods and as a packaging film. It is slowly digested in humans.

It is water soluble, with molecular weights in the range 5000–900,000 g mol⁻¹, with straight unbranched chains, and behaves as a very flexible molecule, with properties of a 'random-coil' (with a molecular persistence length L_p of approximately 2 nm) depending on the combination of sedimentation coefficient and intrinsic viscosity measurements. It has been proposed as a 'standard polysaccharide' because its behavior resembles random coil behavior, and it is readily obtainable in a very reproducible

Fig. 8 Structure of pullulan and its repeating unit maltotriose (reproduced with permission from Farris, S., *et al.*, 2014. Journal of Applied Polymer Science 131, 1–12). The basic monomer (D-anhydroglucose) is also depicted, with the position of each carbon atom indicated by a number.

form so that it can be used for comparative tests with other polysaccharides. The idea is presumably that deviation from pullulan type behavior must imply a more complex structure. It might also be used to standardize instruments. The solutions in water are liable to bacterial attack, with rapid degradation of the molecular weight, and preservatives such as azide may be needed.

Dextrans

Bacterial dextrans are produced in substantial quantities by *Leuconostoc mesenteroides* and are familiar to laboratory workers as the basis for cross-linked dextran beads used in gel filtration columns. They are mostly $\alpha(1\rightarrow6)$ -D-glucopyranosyl polymers with molecular weights up to $\sim 1 \times 10^6 \text{ g mol}^{-1}$ more or less branched through $1\rightarrow2$, $1\rightarrow3$, or $1\rightarrow4$ links. In most cases the length of the side chains is short, and branched residues vary between 5% and 33%. The major commercial dextran is about 95% $1\rightarrow6$ linked and 5% $1\rightarrow3$ linked (Fig. 9), and is made from selected strains of *Leuconostoc*. After ethanol precipitation from the culture medium, acid hydrolysis is used to reduce the overall molecular weight, though fungal dextranases can also be used. The product with an average molecular weight of about $60,000 \text{ g mol}^{-1}$ is used in medicine as a blood extender, while fractions of defined molecular weights (e.g., the Pharmacia T-series, e.g., T-500 Dextran, which stands for dextran of weight average molecular weight $500,000 \text{ g mol}^{-1}$) are familiar in laboratories and to some extent, like the pullulan P-series, serve as polysaccharide standards in molecular weight calibrations. “Blue dextran” is a well-known marker for the void volume in gel filtration studies. Dextrans are also used as part of incompatible phase separation systems, usually with polyethylene glycol. Their solubility in both aqueous and non-aqueous media renders them good membrane formers using electrospinning techniques.

Fig. 9 Chemical structure of the major commercial dextran, which is about 95% $1\rightarrow6$ linked and 5% $1\rightarrow3$ linked.

Dextrans have found very wide application in laboratory work because they are particularly free from positive interactions with proteins. The interactions can be almost entirely characterized as co-exclusion. This has found application, like in the case of pullulans, in calibrating gel filtration media, but cross-linked dextran gels show other effects. For example, they swell and shrink in a way related to the osmotic pressure of the solvent system, and can be used to make miniature osmometers.

Scleroglucan and Schizophyllan

A consideration of microbial polysaccharides would not be complete without at least a brief consideration of two fungal polysaccharides that are attracting increasing commercial interest: the weak-gelling scleroglucan and schizophyllan systems. They are both large, neutral polysaccharides of weight average molecular weights, M_w , (as largely established by light scattering techniques) $\sim 500,000 \text{ g mol}^{-1}$, with a greater diversity being reported for scleroglucan. X-ray diffraction studies indicate that they exist as hydrogen-bond-stabilized triple helices, stabilized by hydrogen bonds with resultant extrarigid rod-like properties in solution; they have virtually the largest persistence lengths known for polysaccharides: $\sim 150 \text{ nm}$ for schizophyllan and 200 nm for scleroglucan. The existence of the triple helix for scleroglucan has been further supported by electron microscopy/light scattering measurements of the mass per unit length, $M_L = 2100 \pm 200 \text{ g mol}^{-1} \text{ nm}^{-1}$, along similar lines to that which supported the duplex model for xanthan as discussed above. The Mark-Houwink viscosity 'a' parameter (a measure of how the intrinsic viscosity of a substance changes with molecular weight and a parameter that reflects the conformation of a macromolecule) of 1.7 for schizophyllans of $M_w < 500,000 \text{ g mol}^{-1}$ is again the highest known for a polysaccharide and is on the rigid rod limit, and these molecules have been used to flocculate small colloidal particles. For chains of $M_w > 500,000 \text{ g mol}^{-1}$ the 'a' parameter falls to ~ 1.2 and corresponds to slightly more flexibility as the polymer length increases.

Chemically also they are very similar, with a backbone of repeating $\beta(1 \rightarrow 3)$ -linked glucose residues:

In scleroglucan every third residue has a $\beta(1 \rightarrow 6)$ -linked D-glucose branch that protrudes from the triple helix (Fig. 10). Using electron microscopy, Stokke and coworkers have demonstrated that certain denaturation-renaturation treatments cause the formation of interesting ring structures or 'macrocycles'. In common with other branched glucans they appear to stimulate an immune response against tumor cells, and, particularly scleroglucans, have been considered for use in cosmetics (as part of skin and hair products), for application in pesticides (to assist binding to foliage), and, along with xanthan and other polysaccharides, for binding water and providing high heat stability in oil well drilling fluids.

Bacterial Alginates

Structure and Production

Alginate is now known to be a whole family of linear copolymers containing blocks of (1,4)-linked β -D-mannuronate (M) and α -L-guluronate (G) residues. The blocks are composed of consecutive G residues (GGGGGG), consecutive M residues (MMMMMM), and alternating M and G residues (GMGMGM) (Fig. 11). Alginates extracted from different sources differ in M and G contents as well as the length of each block, and more than 200 different alginates are currently being manufactured. The G-block content of *Laminaria hyperborea* stems is 60%, and for other commercially available alginates is in the range of 14.0–31.0%.

Alginates are copolymers of the residues guluronic acid (abbreviated as Gula or just G) and mannuronic acid (ManA or M), (Fig. 11) and hence under normal solution conditions (except in acidic environments) these molecules are highly charged polyanionic polyelectrolytes. Although commercial alginates derive largely from algal sources there is a large potential for producing tailor-made alginates from bacterial sources, especially if advantage is taken of the genetic tools for controlling the production of the enzymes that are responsible for the synthesis and epimerization (conversion of D-mannuronic (M) to L-guluronic residues (G)) of the polymeric alginate chain (Fig. 12). There appears to be considerable structural diversity (poly-M, poly-G, and poly-MG residues) and our understanding of the genes and the enzyme gene products is much greater for bacterial alginate production compared to the case for seaweed.

The main alginate-producing bacteria that have been studied are *Pseudomonas aeruginosa* and *Azotobacter vinelandii*. *P. aeruginosa* has been the subject of particular attention because of its association with respiratory disease and is found in patients suffering from cystic fibrosis. *A. vinelandii* appears to be the most promising in terms of industrial production because of its stable output of alginate. *P. aeruginosa* alginate has no poly-G residues, (and hence has a low G content) whereas *A. vinelandii* can, like seaweed alginate, possess all three block sequences (poly-M, poly-G, and poly-MG residues). However, all bacterial alginates are O-acetylated to varying degrees:

Fig. 10 Schematic representation of the repeating unit of scleroglucan (a) and schizophyllan (b).

Structural Enzymes

Starting from fructose-6-phosphate the following enzymes are involved: hexokinase; phosphomannose isomerase; D-mannose-1-phosphate guanyl transferase; GDP (guanosine diphosphate)-mannose dehydrogenase; transferase; acetyl transferase; and mannuronan C-5-epimerase. Schemes involving these have been worked out for *A. vinelandii* and *P. aeruginosa*. Key structural genes have been identified in a gene cluster for *P. aeruginosa* with algG encoding for the epimerase and algF the acetylase (Fig. 13).

Possibilities

It may be possible to treat alginate with epimerases to increase the poly-G content, producing a stiffer polymer. In principle this can be done in vivo by the incorporation and expression of genes from a plasmid in an alginate-producing bacterium (Fig. 14). The degree of acetylation is another control point: acetylated mannuronic acids cannot be converted by epimerases from M→G.

Uses of Alginate

Alginate has demonstrated great utility and potential as a biomaterial for many biomedical applications, particularly in the areas of wound healing, drug delivery, in vitro cell culture, and tissue engineering. The most attractive features of alginate for these applications include biocompatibility, mild gelation conditions, and simple modifications to prepare alginate derivatives with new properties. Alginate has a track record of safe clinical uses as a wound healing dressing material and pharmaceutical component, and has been safely implanted in a variety of applications, including islet transplantation for treatment of type 1

diabetes and chondrocyte transplantation for treatment of urinary incontinence and vesicoureteral reflux. A chemically modified alginate has also been widely used as a carrier to promote periodontal regeneration.

Bacterial Hyaluronic Acid

The commercial value of HA far exceeds that of other microbial extracellular polysaccharides. The HA industry is worth an estimated US\$10 billion per year and medical grade HA sells at US\$100,000 per kg. Potentially the most interesting of the glycosaminoglycans, this biopolymer is found in the joints, skin, vitreous humor of the eyes, and umbilical cord of vertebrates; it is also produced by *Staphylococcus* and some *Streptococci*. The HA layer may enable virulent strains of *Streptococci* to attack immune systems of higher organisms unrecognized.

Structure

HA is a linear polymer consisting of alternating β -(1→4) N-acetyl-D-glucosamine (GlcNAc) and β -(1→3) D-glucuronic acid (GlcUA), resulting in stiff chains due to strong interchain hydrogen bonding and water bridges between acetamido and carboxylate groups (Fig. 15). HA therefore adopts a conformation between that of a random coil and a rigid rod in dilute solution.

Fig. 15 Structure of disaccharide repeating unit of HA.

Extraction and Production

Industrial manufacturing of HA is based on two main processes, the extraction from animal tissues and microbial fermentation using bacterial strains. Both technologies produce polydisperse high molecular weight HA for biomedical and cosmetic applications. In the past decade a new technology emerged using isolated HA synthase to catalyze the polymerization of the UDP-sugar monomers (UDP: Uridine diphosphate). This novel enzymatic technology for HA synthesis is very versatile allowing producing both high M_w HA and HA oligosaccharides with defined chain length and low polydispersity. Production of monodisperse HA oligosaccharides on milligram-scale using two single-action mutants of the *Pasteurella multocida* HA synthase was demonstrated, but large scale production was not achieved yet. A comparative analysis of established and emerging technologies for high M_w HA production is listed in Table 2.

HA is commercially extracted from rooster combs or by microbial fermentation by *Streptococcus* bacteria (e.g., *Streptococcus zooepidemicus*). The fermentation medium typically includes yeast, glutamine, mineral salts (sodium chloride, potassium hydrogen phosphate, and magnesium sulfate), and glucose.

HA quality, in terms of productivity and molecular weight, has been studied under various conditions: temperature; pH; agitation speed; and aeration rate. These experiments demonstrated that under non-optimal growth conditions HA is produced in larger amounts and is of higher molecular weight. It should be noted that HA production greater than $\sim 5\text{--}10\text{ g L}^{-1}$ is impractical due to the high viscosity of the medium.

Table 2 Comparison of technologies for production of HA.

Name	Advantages	Disadvantages
Extraction from animal materials	Well-established technology Available raw material at low costs Product with very high M_w up to 20 MDa Natural product	Variation in product quality Risk of polymer degradation Risk of contamination with protein, nucleic acids, and viruses Extensive purification needed Low yield
Microbial fermentation	Mature technology High yield Product with high M_w (1–4 MDa)	Use of genetically modified organism (GMO) Risk of contamination with bacterial endotoxins, proteins, nucleic acids, and heavy metals
Enzymatic synthesis	Versatile technology Control of the MW of the products. Products up to 0.55–2.5 MDa and also defined oligosaccharides can be obtained No risks of contamination Constant product quality	Emerging technology in development stage Technological and economic viability must still be demonstrated

Properties

Due to its high molar mass of $\sim 1\text{--}3 \times 10^6 \text{ g mol}^{-1}$ and semiflexible coil conformation, HA behaves as a non-Newtonian solution even at low concentrations and the critical coil overlap concentration c^* has been reported to be molecular weight dependent where $c^* \times Mw \approx 2800 \text{ g}^2 \text{ mL}^{-1} \text{ mol}^{-1}$ and therefore we enter the semidilute regime at approximately 1.5 g L^{-1} and the concentrated regime (independent of molecular weight) at $>15 \text{ g L}^{-1}$. HA molecules of high molecular weight have also been shown to have mucoadhesive and anti-inflammatory effects and patients require less frequent injections of higher molecular weight material for arthritis treatment by viscosupplementation, which is important in patient's acceptance of a treatment.

Modification

Chemically modified HAs are available commercially, examples of which include HA benzyl esters (Fidia farmaceutici, Albano Terme, Italy) and divinyl sulfone cross-linked HA (Genzyme, Cambridge, United States). Internally cross-linked (or autocross-linked) HA molecules have also been prepared. HA nanofibers for wound healing are also commercially available (CPN, Dolní Dobrouč, Czech Republic). Modification in terms of molecular weight and molecular weight distributions has also been achieved by means of changes to the growth medium.

Genetic modification of the non-hyaluronic-acid-producing bacteria is an important development in bacterial HA production. The introduction of the *hasA* gene into *Escherichia coli* or *Bacillus subtilis* results in the production of HA and although there is no improvement in quality (in terms of molecular weight and yield) any possible contaminations by streptococcal exo- and endotoxins are eliminated and HA produced by *B. subtilis* has received GRAS (generally regarded as safe) status and should be released in the market in the near future.

Uses

HA is used extensively in the medical, cosmetic, and food industries and its applications have been reviewed recently. The most important industrial applications include the following (Table 3):

1. Viscosurgery – protects delicate tissues during surgical interventions, for example, ophthalmological surgery.
2. Viscosupplementation – supplements tissue fluids, for example, the replacement of synovial fluid in arthritis. Higher molecular weight material requires fewer injections.
3. Viscoaugmentation – used widely in cosmetic surgery to fill tissue spaces.
4. Viscoseparation – prevention of connective tissue surface adhesion after injury or surgery, thereby causing less scarring.
5. Drug delivery – HA microspheres for controlled drug delivery.

Although not strictly speaking HA, the high molecular weight HA-like bacterial exopolysaccharide from *Vibrio diabolis*, a bacterium from deep-sea hydrothermal vents, shows great potential in bone healing.

Polysaccharide Vaccines

No survey of microbial polysaccharides would be complete without reference to the use of polysaccharides in the production of vaccines against serious diseases. Certain types of pathogenic bacteria such as from *Streptococcus pneumoniae*, *Neisseria meningitidis* (Meningococcus), and *Haemophilus influenzae* type B, besides producing harmful or dangerous toxins also produce high molecular weight CPSs, which themselves appear harmless. They do though help the bacterium establish an infection and help hide cell surface components from immune recognition and complement activation. Purified extracts of polysaccharides may themselves be

Table 3 Biomedical and pharmacological applications of HA

Area	Application	Example
Biomedical	Orthopedic surgery	Arthritis
	Rheumatology	Osteoarthritis
	Ophthalmology	Eye surgery
	Otolaryngology	Treatment of vocal fold

Fig. 16 N-acetyl neuraminic acid.

immunogenic and can be used at least in principle to produce immunity against the organism that is producing them. As a result, vaccines against some of these organisms are now available.

The polysaccharides themselves consist of repeat sequences of saccharide residues. One residue that appears frequently is N-acetyl neuraminic acid (Fig. 16), a type of 'sialic acid'.

This residue is common on the surface of membrane glycoproteins and also on mucosal surfaces, so considerable care has to be taken against possible autoimmunity problems. A more serious problem with polysaccharide vaccines is that their effects are not generally long lasting: the repeat sequences produce a T-cell-independent IgM rather than IgG response in infants with little immunological memory effect and are ineffective for infants <2 years. To counter this there has been a lot of recent work on the development of conjugate vaccines where the polysaccharides – or repeat sequences from them – are covalently attached via a linker to an appropriate protein carrier usually based on a bacterial toxoid from diphtheria or tetanus (Fig. 17).

Such conjugates have been successful in enhancing IgG antibody production and stimulating T-cell-dependent immunity against diseases such as meningitis. Two recent articles from the National Institute of Biological Standards in London provide an excellent description of current developments in this area.

In generating these vaccines important issues have to be addressed about the reproducibility of preparations with regard to not only antigenicity and chemical purity but also physical properties including molecular weight and molecular weight distribution limits, and in this regard the use of techniques – with correctly established operating procedures – like SEC-MALLs, analytical ultracentrifugation, viscometry for physical characterization, and NMR and GC mass spectroscopy for chemical characterizations will become increasingly important. This highlights the increasing difference in characterization requirements for a microbial polysaccharide for food use, such as xanthan, and those for biomedical pharmaceutical use, with vaccines as the outstanding example.

Fig. 17 Schematic conjugate vaccine showing capsular polysaccharide (CPS) fragments coupled to an appropriate carrier protein. Reproduced from Ward, J., Lieberman, J.M., Cochi, S.L., 1994. *Haemophilus influenza* vaccines. In: Plotkin, S.A., Mortimer, E.A. (Eds.), *Vaccines*, Philadelphia: Saunders & Co, pp. 337–386 with permission from W.B. Saunders & Co.

Conclusion

The microbial production of polysaccharides is providing a valuable and cost-effective supply of valuable materials for a wide range – potential wide range – of uses, including food and pharmaceuticals because of the absence of or virtually no known toxicity problems. The relative simplicity of bacterial genetics as compared to that for higher organisms renders the manipulation of the production system much easier as we have seen for alginates. Furthermore, the virtual lack of toxicity is providing hope in the development of effective conjugate vaccines against serious disease, provided, issues concerning autoimmunity and product reproducibility are properly taken care of.

Glossary

Antiterminator RNA element that prevents the activity of an attenuator.

Attenuator Terminator located in the leader region of a transcriptional unit, used to regulate expression of downstream genes.

Autogenous regulation Regulation of a gene by the product encoded by that gene.

cis-Acting element Element that affects only a region with which it is physically connected (e.g., a DNA site).

Coupling Coordination of cellular processes, for example, transcription and translation.

Leader peptide Short peptide encoded in the leader region of a transcriptional unit.

Leader region Segment of a gene between the transcription initiation site and the start of the coding sequence.

Leader RNA Segment of an RNA that is upstream of the first coding sequence.

Ribosome binding site (RBS) Translation initiation signal, comprised of SD plus start codon (usually AUG, GUG, or UUG).

Shine–Dalgarno sequence (SD) Binding site for the 30S ribosome on an mRNA for translation initiation.

Terminator Signal for RNA polymerase to stop transcription and release the DNA template and the nascent transcript.

trans-Acting factor Factor or substance that can act at a distance within a cell (e.g., a protein or RNA that can diffuse to a different site).

Transcription elongation complex RNAP as it moves along the DNA template, after leaving the promoter site.

Abbreviations

5' UTR	5' Untranslated region
PNPase	Polynucleotide phosphorylase
RBS	Ribosome binding site
RF2	Release factor 2
RNAP	RNA polymerase
SAM	S-Adenosylmethionine
SD	Shine–Dalgarno sequence
sRNAs	Small regulatory RNAs
tRNA ^{Trp}	Tryptophanyl-tRNA

Defining Statement

Posttranscriptional gene expression events that occur after RNA polymerase (RNAP) leaves its promoter site offer many opportunities for regulation in bacteria. This article reviews some of these mechanisms, including modulation of premature termination of transcription, mRNA degradation, and translation initiation, and also illustrates each class with specific examples.

Introduction

Regulation of gene expression at the level of transcription initiation is of obvious importance in all biological systems. Recognition of the promoter site on the DNA by RNA polymerase (RNAP), melting of the DNA, synthesis of the first few nucleotides of the transcript, and escape from the promoter site all represent important steps at which transcription initiation can be controlled. However, it has become increasingly obvious that events that occur after RNAP leaves its promoter site offer many additional opportunities for regulation, and mechanisms that affect these events are considered to be posttranscriptional regulatory events, although certain of these mechanisms affect transcript levels. Premature termination of transcription results in failure to synthesize the complete transcript. Modulation of transcript degradation, which can begin before the transcript has been fully synthesized, can have a major effect on expression of the encoded genes. The efficiency with which an mRNA is translated can dramatically affect the

synthesis of the encoded protein product and can also affect the rate of transcript degradation. This article reviews mechanisms of gene regulation that occur after transcription initiation in bacteria. Specific examples are described to illustrate each class of event.

Regulation of Premature Termination of Transcription

One of the most common mechanisms of posttranscriptional gene regulation involves positioning of a transcription termination signal (or terminator) in the region between the promoter and the start of the regulated coding sequence. This region is commonly called the leader region in bacteria, and corresponds to the 5' untranslated region (5' UTR) in eukaryotic cells; because this region can be translated in bacteria to yield a peptide product, as described below, leader region is a more general term. Termination signals located within leader regions are called attenuators, as their role is to attenuate synthesis of the full-length transcript. Modulation of the activity of the terminator element in response to an appropriate physiological signal therefore can be used to determine the amount of full-length transcript made and the level of expression of the gene(s) that are downstream of the attenuation site. A wide variety of regulatory mechanisms of this type have been uncovered. Many of these mechanisms depend on effects on the folding of the nascent RNA transcript, while others affect the ability of the transcriptional machinery to recognize termination signals.

Termination Mechanisms

Two types of transcriptional terminators have been described in bacteria. Detailed biochemical analyses have been carried out primarily in *Escherichia coli*, but it appears that the basic features of terminators, and therefore their utilization as a regulatory target, are conserved in many groups of bacteria. Both types of termination events require features of the nascent RNA transcript that emerges from the elongating RNAP that the terminator is attempting to halt. The most common class of terminator elements are called intrinsic (or factor-independent) terminators. These termination signals are defined biochemically by their activity in a purified in vitro transcription system in the absence of any cellular factors other than RNAP. Intrinsic terminators are comprised of a G + C-rich RNA helix, usually 7–8 nt in length, immediately followed by a stretch of U residues in the nascent transcript. Positioning of RNAP so that the U residues form the RNA–DNA hybrid within the enzyme, and the RNA helix abuts the distal portion of the enzyme, results in destabilization of the transcription complex and termination. The role of the helix has been proposed to involve pushing forward on RNAP to remove the 3' end of the transcript from the active site of the enzyme, while the U–A RNA–DNA hybrid is likely to assist in complex destabilization. Regulation of the activity of intrinsic terminators often occurs by alternate folding of the nascent RNA transcript, so that the region necessary for formation of the 5' side of the terminator helix is instead sequestered in an alternate structure, termed an antiterminator. Intrinsic terminators can also be affected by increasing the processivity of RNAP, which reduces the sensitivity of the transcription complex to destabilization, at least in part because RNAP passes through the termination site before the RNA helix can exert its destabilizing effect.

The second class of bacterial termination signals are designated Rho-dependent (or factor-dependent) terminators, based on the requirement for an additional protein (Rho factor) for termination activity in vitro. Rho binds to the nascent RNA transcript, moves along the RNA until it encounters RNAP (usually at a pause site), and promotes destabilization of the transcription complex, probably by removal of the 3' end of the transcript from the active site of the enzyme. Binding sites for Rho on the RNA, designated *rut* (Rho utilization) sites, are poorly conserved, but are generally unstructured, with overrepresentation of C and U residues and underrepresentation of G residues. Regulation of Rho-dependent termination usually occurs by sequestration of the *rut* site on the RNA to prevent Rho binding or by modification of the transcription complex to increase processivity of RNAP, interfering with the ability of Rho to reach the transcription elongation complex.

Regulation of Termination by Modulation of Nascent Transcript Structure

As noted above, the activity of intrinsic terminators is dependent on folding of the nascent transcript as it emerges from the RNA exit channel of RNAP into a helix that plays a crucial role in destabilization of the transcription elongation complex. Formation of the helix therefore represents an effective target for regulation of termination activity. A variety of factors can interact with the nascent RNA to determine whether it folds into the terminator helix, in most cases by determining whether the terminator helix or a competing antiterminator helix is formed. The relative stabilities of the terminator and antiterminator helices play a major role in determining the sensitivity of the RNA to the interacting factors, and whether binding of the factor results in attenuation of transcription or increased synthesis of the full-length transcript. Interacting factors that have been demonstrated to affect leader region terminator activities include translating ribosomes, RNA-binding proteins, *trans*-acting RNAs, and small molecules.

Leader peptide attenuation systems

The classic model for regulation of nascent transcript structure to control termination involves the presence of a short peptide coding sequence within the 5' region of the transcript. The processivity of the ribosome during translation of this peptide coding sequence modulates the structure of the RNA, therefore affecting both pausing of the transcription elongation complex from which this nascent RNA is emerging, and the folding of this transcript into competing terminator and antiterminator elements. Processivity of the ribosome can in turn be affected by the sequence of the nascent peptide itself. For example, in systems like the *E. coli trp* operon, which encodes gene products involved in tryptophan biosynthesis, the peptide coding sequence includes tandem tryptophan

Fig. 1 Leader peptide-mediated effects on gene expression. (A) Transcriptional attenuation in the *E. coli trp* operon. Translation of the leader peptide coding sequence (red box), which includes two tandem tryptophan codons (**), results in stalling of the ribosome when availability of charged $tRNA^{Trp}$ is low; this allows the nascent RNA to form into an antiterminator structure (AT) that permits RNAP (yellow ovals) to proceed through the attenuator site, and transcribe the downstream gene (blue box). High availability of charged $tRNA^{Trp}$ causes efficient leader peptide (LP, red line) translation, and the movement of the ribosome (green ovals) causes folding of the leader RNA into the terminator helix (T); this prevents synthesis of the full-length transcript, and expression of the downstream genes is repressed. (B) Regulation of Rho-dependent transcription termination in the *E. coli tna* operon. The ribosome translating the leader peptide coding sequence stalls in the presence of high tryptophan, preventing binding of Rho (purple hexagon) to the nascent RNA; this results in expression of the downstream genes. When tryptophan is low, the ribosome completes synthesis of the leader peptide (red line) and releases the RNA, which allows access of Rho and Rho-dependent termination. (C) Chloramphenicol-dependent translational control of the *cat* gene. In the absence of chloramphenicol, the leader peptide coding sequence is efficiently translated, and the SD sequence of the downstream *cat* gene is sequestered in an inhibitory structure. Low concentrations of chloramphenicol cause the ribosome translating the leader peptide to stall, which unfolds the mRNA structure and allows access of a second ribosome to the SD of the downstream gene.

codons (Fig. 1A). The presence of these tryptophan codons renders translation of the leader peptide coding region sensitive to the availability of charged tryptophanyl-tRNA ($tRNA^{Trp}$). Reduced abundance of tryptophan results in a reduction of charged $tRNA^{Trp}$, causing the translating ribosome to stall as it attempts to translate the tandem tryptophan codons. The stalled ribosome allows the unoccupied RNA ahead of it to fold into an antiterminator element, which prevents formation of the more stable terminator helix, therefore resulting in readthrough of the leader region transcription terminator site (or attenuator), and synthesis of the full-length transcript. The presence of a large pool of charged $tRNA^{Trp}$ results in efficient translation of the leader peptide coding sequence. Rapid progress of the ribosome through the leader peptide coding region prevents formation of the antiterminator, and allows formation of the terminator helix and attenuation of transcription. Synthesis of the full-length transcript, and therefore expression of the tryptophan biosynthesis genes, therefore occurs only when cells are limited for charged $tRNA^{Trp}$, which signals a requirement for increased tryptophan biosynthetic activity. This type of mechanism is easily converted to allow recognition of a different charged tRNA by changing the sequence of the leader peptide itself, so that the tryptophan codons in the nascent RNA are replaced with clusters of codons specifying a new amino acid (e.g., the leader peptide of the histidine biosynthetic operon contains multiple histidine codons).

This type of transcription termination control mechanism is often superimposed on a second level of regulation. For example, initiation of transcription of the *E. coli trp* operon is regulated by the TrpR DNA-binding protein, which blocks binding of RNAP to the promoter region and represses transcription initiation when tryptophan levels are high. The combination of the two regulatory mechanisms allows sensing of both free tryptophan (by TrpR) and charged tRNA^{Trp} (by the ribosome that is translating the leader peptide coding sequence). This results in a highly sensitive regulatory response that prevents wasteful expression of *trp* operon genes when tryptophan is abundant and also ensures an adequate supply of charged tRNA^{Trp} for efficient protein synthesis.

Leader peptide transcription attenuation mechanisms are dependent on the tight coupling of transcription and translation in bacteria, where binding of the 30S ribosomal subunit to an RNA transcript can occur as soon as the RBS emerges from the transcription elongation complex. Translation of the leader peptide coding sequence must be coordinated with pausing of RNAP during synthesis of the leader region of the transcript to allow a response to ribosome positioning before RNAP escapes from the attenuator region or terminates transcription. In the *E. coli trp* system, a specific signal in the leader RNA causes RNAP to pause, which allows translation of the leader peptide to initiate; the translating ribosome releases RNAP from the pause site, so that transcription and translation now proceed in tandem unless the ribosome is stalled by low abundance of charged tRNA^{Trp}.

Coupling of transcription and translation is also crucial to the *E. coli pyrB1* attenuation mechanism. This operon encodes products involved in biosynthesis of pyrimidine nucleotides, and direct sensing of NTP abundance by the transcription elongation complex is used to repress expression when pools of these nucleotides are high. Pausing of RNAP during transcription of segments of the leader region containing runs of C and U residues is triggered by limitation for pyrimidine nucleotides. This pause allows time for initiation of translation of a leader peptide coding sequence, and positioning of the translating ribosome on the nascent RNA prevents formation of the terminator helix. When pyrimidine nucleotides are abundant, rapid progress of RNAP through the pause sites before the ribosome can bind and occlude the terminator allows termination, and repression of *pyr* operon expression, to occur. As in the *E. coli trp* system, the position of a translating ribosome relative to the transcribing RNAP determines the structure of the nascent RNA, and therefore regulates whether transcription is attenuated within the leader region. In the *pyrB1* system, RNAP serves as the molecular sensor for the effector molecule (pyrimidine nucleotides), whereas in the *E. coli trp* system, the translating ribosome senses charged tRNA^{Trp}; in both cases, the molecular sensors directly monitor their biochemical substrates while carrying out their normal biological reactions.

Regulation of RNA structure by RNA-binding proteins

A number of systems have been described in which binding of a regulatory protein to a leader RNA affects formation of an intrinsic terminator. These proteins can act negatively to stimulate termination (i.e., the terminator is inactive in the absence of the protein, binding of which promotes termination) or positively to increase readthrough of the attenuation site (i.e., the terminator is active in the absence of the protein, binding of which prevents termination and allows synthesis of the full-length transcript). The best characterized system in which a protein promotes terminator formation is the *Bacillus subtilis trp* operon, which encodes gene products involved in tryptophan biosynthesis (Fig. 2A). The *trp* leader RNA terminator helix is relatively unstable, and its formation is prevented by folding of the RNA into the more stable antiterminator structure, which includes residues necessary for terminator helix formation. Binding of the regulatory protein, designated TRAP, sequesters a region of the RNA that participates in formation of the antiterminator element and allows the less stable terminator helix to form, which causes termination. The RNA-binding activity of TRAP requires association with tryptophan, which serves as a corepressor. Termination therefore occurs when tryptophan is abundant, as described above for the *E. coli trp* operon, but in this case the molecular mechanism for sensing tryptophan availability involves binding of tryptophan to the regulatory protein rather than monitoring of charged tRNA^{Trp} during leader peptide translation. Charging of tRNA^{Trp} is sensed indirectly in *B. subtilis* through a second regulatory protein, designated anti-TRAP, which is expressed in response to a decrease in charged tRNA^{Trp} (via the T-box mechanism; see below) and antagonizes TRAP activity, allowing increased *trp* operon expression. This dual measurement of both free tryptophan and charged tRNA^{Trp} is similar to that observed in *E. coli*, although different molecular mechanisms for sensing the effector molecules are employed.

Whereas the *E. coli trp* and *pyr* operons use leader peptide attenuation regulatory mechanisms, the *B. subtilis trp* and *pyr* operons both use an RNA-binding protein to control transcription termination. The *B. subtilis pyr* system is similar to the TRAP system, but has an added complexity in that the PyrR regulatory protein (in the presence of pyrimidine nucleotides as corepressor) binds to and stabilizes a leader RNA element that sequesters sequences necessary for formation of the antiterminator. Binding of PyrR prevents antiterminator formation and allows the less stable terminator helix to form. The PyrR-binding site therefore serves as an “anti-antiterminator element,” because it antagonizes the antiterminator element. This differs from the TRAP system, in that TRAP directly sequesters sequences involved in formation of the antiterminator without stabilizing an alternate RNA element. The reliance of both the *E. coli trp* and *pyrB* mechanisms on coupling of transcription and translation, while the analogous mechanisms in *B. subtilis* instead use an RNA-binding protein to modulate expression, may reflect differences in the efficiency of coordinating transcription and translation in these two organisms (and by extension, their close relatives).

RNA-binding proteins can also promote antitermination. Systems of this type utilize leader RNAs in which the terminator helix is more stable than the competing antiterminator, so that termination is the default state that occurs in the absence of protein binding. Binding of the protein to the RNA stabilizes the antiterminator element, which sequesters sequences that would otherwise participate in formation of the terminator helix. An example of this type of system is provided by the *E. coli bgl* operon, which is involved in utilization of β -glucoside sugars (Fig. 2B). The BglG protein acts as the regulatory protein, and its

Fig. 2 Regulation of transcription attenuation by RNA-binding proteins. (A) Protein-dependent attenuation in the *B. subtilis trp* operon. When tryptophan levels are low, the *trp* operon leader RNA folds into an antiterminator element (AT) that allows RNAP (yellow ovals) to proceed past the attenuation site and transcribe the downstream gene (blue box). High tryptophan allows TRAP protein–tryptophan complex (pink circle) to bind to the leader RNA; TRAP sequesters sequences necessary for antiterminator formation, which allows formation of the terminator helix (T) and repression of downstream gene expression. (B) Protein-dependent antitermination in the *E. coli bgl* operon. In the presence of the substrate sugar, the BglG RNA-binding protein (pink circle) binds to and stabilizes the antiterminator element (AT), which allows transcription to continue past the termination site. In the absence of the substrate sugar, BglG protein is phosphorylated (P) and unable to bind the RNA; the terminator helix (T) forms, and transcription of the downstream gene is repressed.

RNA-binding activity is induced when the substrate sugar is present. The RNA target of the BglG protein includes residues necessary for formation of the terminator helix, so that BglG binding prevents termination and allows expression of downstream genes involved in sugar utilization. Unlike the TRAP or PyrR proteins, BglG does not directly bind the effector molecule but is instead dephosphorylated by BglF, the transporter for the sugar substrate, when the sugar is present. Dephosphorylation of BglG by BglF allows BglG to dimerize, which is required for RNA-binding activity. BglF therefore serves as the sensor of the effector molecule, and transmits information about effector availability to BglG via phosphorylation, in a manner analogous to that used by two-component regulatory systems in which phosphotransfer between a sensor kinase and a response regulator allows transmission of a regulatory signal from one protein to another. Several sugar utilization operons in *B. subtilis* are regulated by mechanisms similar to the *E. coli bgl* system.

Control of termination by RNA–RNA interactions

The ability of RNA molecules to base-pair with other RNA molecules provides another mechanism by which the structure of a leader transcript can be modulated, and RNA–RNA interactions have been exploited in a variety of regulatory systems. While most *trans*-acting regulatory RNAs in bacteria affect translation or stability of the target mRNA, binding of a *trans*-acting RNA to the nascent RNA can also affect the ability of the targeted region of the transcript to fold into terminator or antiterminator structures, thereby affecting attenuation or readthrough.

The best-characterized example of this type of mechanism is the T-box system, which is widely used in Firmicutes to control genes involved in amino acid metabolism, including aminoacyl-tRNA synthetase, amino acid biosynthesis, and transporter genes; as noted above, this mechanism also regulates synthesis of the anti-TRAP regulatory protein. Genes regulated by the T-box mechanism exhibit a complex set of conserved structural and primary sequence elements in their leader regions, which include a terminator and competing antiterminator. Embedded at a specific position within this array of conserved elements is a single codon that matches the anticodon of a tRNA that belongs to the amino acid class relevant to the gene product encoded in the coding sequence(s) located downstream of the terminator. For example, the *B. subtilis tyrS* gene, encoding tyrosyl-tRNA synthetase, contains a UAC tyrosine codon at the appropriate position. Binding of the matching uncharged tRNA (e.g., tRNA^{Tyr} for *tyrS*) to the leader RNA, which is determined by base-pairing of the leader region codon with the anticodon of the tRNA, is required to stabilize the antiterminator element by pairing of the four unpaired residues at the 3' end of the tRNA with residues located in a bulge within the antiterminator (Fig. 3A). The interaction of the appropriate uncharged tRNA with the nascent leader

Fig. 3 Regulation of transcription attenuation by *trans*-acting RNAs. (A) tRNA-dependent antitermination in the T-box system. When levels of a specific uncharged tRNA are high, the tRNA (green cloverleaf) binds to the nascent transcript of the gene that senses that tRNA; binding of the tRNA stabilizes an antiterminator element (AT), which allows RNAP (yellow ovals) to transcribe the downstream gene (blue box). When levels of the specific uncharged tRNA are low (i.e., the tRNA is predominantly in the charged state), the leader RNA folds into the terminator helix (T), and transcription of the downstream gene is repressed. (B) RNA-dependent attenuation by antisense RNAs. In the absence of the antisense RNA, an antiterminator element (AT) forms, and RNAP proceeds through the attenuator site and transcribes the downstream gene. Binding of the antisense RNA (green line) sequesters sequences necessary for antiterminator formation, and causes formation of the terminator helix (T) and repression of downstream gene expression.

transcript therefore prevents formation of the terminator helix, and results in increased transcription of the downstream genes. The cognate charged tRNA (e.g., tRNA^{Tyr} aminoacylated with tyrosine) can also interact with the codon region, but is unable to stabilize the antiterminator because of the presence of the amino acid at the 3' end of the tRNA. Codon-anticodon pairing is therefore responsible for selection of a particular tRNA species as the effector for a particular transcriptional unit, and pairing between the tRNA acceptor end and the antiterminator is responsible for discrimination between the uncharged and charged forms of that tRNA. The ability of the cognate charged tRNA to interact with the codon but not the antiterminator results in inhibition of binding of the effector uncharged tRNA, so that the true physiological signal is the relative amounts of uncharged and charged species of a specific tRNA. The cell therefore modulates expression of genes involved in converting a particular tRNA class from its uncharged to its charged state, in response to the substrate-product ratio.

The tRNA-leader RNA interaction and tRNA-directed antitermination have been demonstrated *in vitro* using purified components, which indicates that no factors other than the leader RNA itself are necessary for specific recognition of the cognate uncharged tRNA. The T-box system therefore operates as a riboswitch, in which binding of a specific ligand results in an RNA structural change that regulates expression of a downstream gene (see below). The T-box riboswitch, like systems that utilize leader peptide translation (e.g., *E. coli trp*), monitors the charging of a specific tRNA class to control leader RNA structure; however, while leader peptide transcription attenuation systems monitor only availability of the appropriate charged tRNA, by using a translating ribosome, the T-box system monitors both charged and uncharged tRNA charging, by using direct binding of the tRNA to the nascent RNA transcript.

Several systems have been described in which binding of a *trans*-acting small RNA is proposed to modulate leader RNA structure to promote transcription termination. These systems, which have been analyzed primarily in plasmids, utilize *cis*-encoded antisense RNAs that bind to their target transcripts to, in some way, facilitate formation of the terminator helix, usually by destabilization of a competing antiterminator element (Fig. 3B). Mechanisms of this type often utilize more extensive base-pairing interactions between the regulatory RNA and its target. This role of small RNAs, while so far applicable only to *cis*-encoded RNAs, adds to the diversity of regulatory mechanisms that noncoding RNAs can affect in bacteria (see below).

Metabolite-binding riboswitch RNAs

A number of systems have recently been described in which binding of a small molecule to the nascent RNA transcript results in an RNA structural rearrangement that determines whether the transcript folds into an intrinsic terminator helix or a competing antiterminator structure. Like the T-box system described above, systems of this type have been called riboswitches. In most of these systems, the leader RNA includes an element that serves as an effector-binding "aptamer" domain, which in isolation can

Fig. 4 Regulation of transcription attenuation or translation initiation by riboswitch RNAs. (A) SAM-dependent transcription attenuation in the S-box RNAs. In the absence of SAM, the antiterminator element (AT) forms in the leader RNA, allowing RNAP (yellow ovals) to proceed through the termination site and transcribe the downstream gene (blue box). In the presence of SAM (*), an RNA structural rearrangement causes formation of the terminator helix (T), resulting in attenuation of transcription. (B) SAM-dependent inhibition of translation initiation in the S_{MK}-box RNAs. In the absence of SAM, the SD region of the transcript is available for binding of the ribosome (green ovals), and translation of the downstream gene occurs. Binding of SAM (*) to the leader RNA causes a structural rearrangement that results in sequestration of the SD region, preventing ribosome binding and downstream gene expression.

specifically recognize the cognate ligand. Binding of the ligand usually sequesters a segment of RNA that would otherwise participate in forming the antiterminator element (Fig. 4A). The ligand-binding domain therefore serves as an anti-antiterminator that prevents formation of the antiterminator, and therefore allows termination. Metabolite-binding riboswitches are generally used to regulate genes involved in uptake or biosynthesis of the signal molecule, and represent a type of feedback repression, where accumulation of high amounts of the ligand represses expression of genes that encode proteins involved in increasing the intracellular concentration of that ligand. For example, S-adenosyl methionine (SAM) binds to the S-box riboswitch to repress transcription of genes involved in biosynthesis and uptake of SAM and methionine (which is a substrate for SAM synthesis). A few systems show an opposite arrangement, whereby binding of the ligand results in formation of the antiterminator, and promotes synthesis of the full-length transcript; in systems of this type, the ligand generally is a substrate of the regulated pathway. The metabolite binding riboswitch RNAs exhibit highly specific recognition of their cognate effector molecules, which include vitamins, cofactors, nucleotides, amino acids, and metal ions, as well as an affinity for their target molecule appropriate to the physiological concentration of the effector. As in the T-box system, the effector-dependent RNA conformational change and transcription termination response can be reproduced *in vitro* in the absence of other cellular factors, indicating that the RNA transcript encodes all features necessary for the regulatory mechanism.

Reiterative transcription

As noted above in reference to the *E. coli pyrB1* operon, NTP abundance can affect the processivity of RNAP. The *B. subtilis pyrG* gene represents a system in which limitation for an NTP not only affects pausing but also results in nontemplated addition of residues to the transcript, in a process termed reiterative transcription. In this system, the transcript initiates with three G residues, followed by a C residue. When CTP is abundant, transcription proceeds through this region, and terminates at an intrinsic terminator prior to the start of the *pyrG* coding region. Limitation for CTP results in stalling of RNAP during synthesis of the 5' region of the transcript, and RNAP stalling causes slippage relative to the template DNA and incorporation of a series of extra G residues into the transcript. RNAP eventually escapes from this site and continues transcription into the leader region. The resulting transcript now contains a longer run of G residues that are capable of pairing with C and U residues normally found on the 5' side of the terminator helix. This pairing causes formation of an antiterminator element that is not directly encoded in the DNA template, and arises only from the reiterative transcription event. Reiterative addition of G residues, triggered by starvation of RNAP for CTP, therefore promotes synthesis of the full-length transcript, and *pyrG* expression, when cells are limited for pyrimidine nucleotides. This mechanism, like that of the *E. coli pyrB* operon, utilizes the transcription

complex itself to monitor availability of its NTP substrates, but the mechanistic consequences of specific NTP limitation differ in the two systems.

Regulation of Termination by Modulation of Transcription Complex Activity

All the systems described above involve changes in the structure of the nascent transcript, which arise as the result of interaction of other factors with the RNA, or through changes in the RNA sequence that occur during transcription. Another major class of transcription termination control systems does not utilize structural changes in the nascent RNA but instead involves changes in the behavior of the transcription machinery itself. These systems can modulate the processivity of RNAP or the ability of the termination machinery (i.e., Rho factor) to access the transcription elongation complex.

Protein-dependent changes in transcription complex processivity

The classic example of a system in which binding of a protein to a nascent transcript causes the transcription elongation complex to ignore downstream termination sites is provided by the bacteriophage lambda N-mediated antitermination mechanism. The phage-encoded N protein is responsible for the transition between the earliest stage of phage gene expression (during which only N and another regulatory protein, Cro, are synthesized) and the next stage of gene expression. N binds to specific sites (designated *nut* sites, for N utilization) on transcripts initiating at both the leftward (p_L) and rightward (p_R) major promoters. Once bound to these sites, N nucleates assembly of a complex of host-encoded proteins (the Nus factors, for N usage substance) that interact with RNAP (Fig. 5A). NusA protein binds first, and is sufficient for antitermination at sites close to the *nut* site; formation of a stable complex requires the addition of the remaining factors (NusB, NusG, and ribosomal protein S10). Assembly of the complete complex results in a more processive transcription elongation complex with reduced pausing and reduced termination activity at both Rho-dependent and intrinsic terminators, and this complex remains intact during transcription of long segments of DNA distal to the modification site. This effect has been termed processive antitermination because it allows readthrough of multiple termination sites that are encountered in succession as the transcription complex moves along the DNA.

Bacteriophage lambda uses a second protein-dependent antitermination mechanism to promote the transition to late gene expression, mediated by the phage-encoded Q protein. In contrast to N, Q is a DNA-binding protein that interacts with the nontemplate strand of the DNA in a transcription complex paused just downstream from the late gene promoter. Q-directed antitermination also differs from the N system in that only a single host-encoded factor, the NusA protein, is required. Both the N and the Q systems are conserved in related lambdoid phage.

The lambda N antitermination system also serves as the target of a protein-directed termination system, in which a related phage, designated HK022, encodes a protein (Nun) that is related to N but interferes with N-mediated antitermination, causing failure of the N system and abrogation of the lambda lytic cycle. Nun binds to the *nut* sites on the nascent lambda transcripts and, in complex with the same Nus factors that are utilized by N to promote antitermination, instead promotes transcriptional arrest and termination. It is important to note that Nun does not inhibit N-mediated antitermination only by competing with N for binding to *nut* sites, but instead directly promotes termination at sites immediately downstream from the *nut* sites even in the absence of N. The biological role of the Nun system appears to be to promote HK022 propagation in cells coinfecting with lambda, and HK022 utilizes a different class of antitermination mechanism to carry out its own life cycle (see below).

Fig. 5 Changes in processivity of the transcription elongation complex. (A) In the bacteriophage lambda N system, N protein (pink circle) binds to the *nut* site on the nascent transcript and recruits additional factors (purple circles) that together modify RNAP (yellow ovals) to a complex that is resistant to transcription termination signals; this allows transcription of downstream genes (blue box). In the absence of N, the *nut* site is unoccupied and RNAP stops at termination signals that prevent downstream gene expression. (B) Bacteriophage HK022 uses the *cis*-acting *put* RNA element to modulate the processivity of RNAP, which results in readthrough of termination sites and expression of downstream genes. As the *put* site is always present in the RNA, its antitermination activity appears to be constitutive.

A different mode of protein-dependent modulation of the transcription elongation complex is represented by the RfaH system, which is found in a number of enteric bacteria. RfaH protein interacts with the nontemplate strand of the DNA on the surface of a transcription elongation complex paused at specific *cis*-acting sequences, designated *ops* sites. RfaH, a structural homolog of NusG, remains stably associated with the transcription elongation complex, and increases its processivity in a manner similar to the N and Q systems. This results in readthrough of potential termination sites in the downstream DNA, and thereby stimulates synthesis of longer transcripts and expression of the downstream coding sequences. The RfaH system differs from the phage-encoded systems in that no cellular factors other than RfaH are required. RfaH-dependent antitermination is important for a number of processes involved in virulence in *E. coli* and its relatives.

RNA-dependent changes in transcription complex processivity

As noted above, phage HK022 utilizes the Nun protein not to mediate antitermination during expression of its own genome, but rather to prevent N-mediated antitermination by a coinfecting lambda phage. As for other lambdoid phage, antitermination is required for HK022 to advance into the lytic cycle, but in this case *cis*-encoded elements within the nascent transcript are responsible for readthrough of the early termination sites. Transcription originates from two divergent promoters (as described for lambda), and RNA elements (designated *put* sites) located downstream from the two promoters act in *cis* to promote readthrough of downstream termination sites and allow expression of genes located distal to the terminators (Fig. 5B). The *put* sites are each comprised of two stem-loop elements, both of which are required for antitermination activity. These RNA elements are sufficient to promote antitermination in the absence of any HK022-encoded protein factors, and no host-encoded factors are required, in contrast to the lambda system. The *put*-encoded RNA elements interact directly with the β' -subunit of RNAP, and specific mutations in β' block *put*-mediated antitermination (and HK022 growth) without obvious effects on *E. coli* transcription or lambda growth. HK022 *put*-dependent antitermination appears to be constitutively active, as the *put* sites are always present in the nascent transcripts; this differs from the lambda N system, which allows regulation of downstream gene expression in response to N availability. Although the detailed mechanism of *put*-mediated antitermination remains to be elucidated, it appears that its function is similar to that of N protein in that it promotes both reduced pausing by the transcription elongation complex and processive antitermination.

Interference with Rho binding

Rho protein is the key factor responsible for mediating Rho-dependent transcription termination, and the requirement for interaction of Rho with the nascent transcript at *rut* sites provides a target for regulation. Binding of other factors to the transcript can affect the ability of Rho to access its binding sites on the RNA. The clearest example of a regulatory mechanism of this type is provided by the *E. coli tna* operon, encoding tryptophanase, which is involved in the utilization of tryptophan as a source of carbon and nitrogen. The tryptophanase coding region is preceded by a leader region that includes both a Rho-dependent termination site and a short peptide coding region (Fig. 1B). When tryptophan levels are low (conditions under which *tna* operon expression is repressed), translation of the leader peptide coding sequence proceeds normally, and the ribosome and nascent peptide are released. Under these conditions, the Rho-dependent terminator in the leader region is active, and transcription is attenuated. When tryptophan levels are high, signaling a need for *tna* operon expression, a ribosome translating the *tnaC* region in the nascent transcript stalls and occludes the *rut* site within the leader region; Rho binding is prevented, and synthesis of the full-length transcript occurs, which allows production of tryptophanase. Tryptophan-dependent stalling of the ribosome during *tnaC* translation depends on specific features of the *tnaC*-encoded peptide, which in the presence of free tryptophan interacts in *cis* within the exit channel of the translating ribosome to inhibit peptidyl transferase activity, thereby preventing translocation. The requirement for free tryptophan to promote stalling of the ribosome–nascent peptide complex provides the sensitivity to tryptophan concentration necessary for an appropriate physiological response, since degradation of tryptophan is advantageous only when tryptophan is highly abundant.

Recent studies have demonstrated that metabolite-binding riboswitches, which usually operate by effects on intrinsic terminators or translation initiation, also can affect Rho-dependent termination. An example is provided by the *E. coli ribB* operon, which is involved in riboflavin biosynthesis and is repressed by flavinmononucleotide (FMN). Regulation was proposed to occur via sequestration of the SD region of the transcript; however, in vitro studies revealed that FMN stimulates the activity of a terminator, only in the presence of Rho protein. The importance of Rho in this regulatory mechanism is supported by the reduction of repression (and termination) in vivo in the presence of bicyclomycin, a Rho inhibitor. The mechanism by which FMN binding and the resulting RNA structural rearrangement interferes with Rho activity remains to be determined.

Rho-dependent termination can also be regulated by the abundance of Rho protein itself. This sensitivity to Rho availability is utilized in autogenous regulation of *rho* gene expression. The *rho* gene contains several Rho-dependent termination sites, and synthesis of the full-length transcript is repressed when the cellular concentration of Rho protein is high. This represents a classical autorepression response that makes use of the biological function of the regulated protein to control its own synthesis.

Effects of Premature Termination on Upstream Gene Expression

While termination in a leader region is normally considered to control expression of coding sequences located downstream of the termination site, by determining whether the transcript includes those downstream regions, it is also possible for termination mechanisms to affect expression of genes located upstream of the termination site, in a process termed retroregulation. The classical example of this type of effect is observed in bacteriophage lambda, where N-mediated antitermination not only promotes

transcription of genes downstream from the termination sites but also results in downregulation of the *int* gene, which is located upstream of one of the N-regulated termination sites. The *int* gene encodes the integrase necessary for integration of the lambda genome into the host chromosome, and its repression when N is active is a component of the switch between the lysogenic and lytic cycles. In the absence of N, the *int* transcript terminates at the intrinsic terminator site located at the end of the *int* coding sequence. N-mediated readthrough of this termination site results in synthesis of an extended transcript that now includes a new element (designated *sib*) that is sensitive to cleavage by the endoribonuclease RNase III. RNA cleavage at the *sib* site triggers the degradation of the mRNA region 5' to the *sib* site by exonucleolytic degradation from the 3' end released by RNase III, which results in decreased *int* mRNA levels. N-mediated antitermination therefore causes decreased stability of the *int* transcript, despite the fact that *int* is encoded upstream of the termination site targeted by N. It is likely that this type of regulatory effect occurs in other polycistronic transcripts in which the regulated terminator is located between coding sequences, especially since the presence of the helix of an intrinsic terminator often stabilizes transcripts by inhibiting access of the RNA degradation machinery (see below). Extension of the transcript by antitermination separates the 5' coding region from the terminator element, which can provide additional targets for endoribonuclease cleavage and RNA destruction.

Regulation of mRNA Stability

The net amount of an mRNA transcript in a cell at any given time arises from the combined effects of transcript synthesis and transcript destruction. Changes in the stability of a particular RNA can have as great an effect on expression of the encoded gene product(s) as changes in the synthesis rate of that RNA. RNA degradation in *E. coli* occurs through the combined activity of a series of 3'–5' exonucleases, and endonucleases that cleave within the RNA to provide new 3' ends for attack by the exonucleases. Structure at the 3' end of a transcript, as occurs when the 3' end of the RNA is generated by an intrinsic terminator, inhibits access of the 3'–5' exonucleases. Polyadenylation of the transcript by poly(A) polymerase (the product of the *pcnB* gene) provides a site for 3'–5' exonuclease recruitment. While no 5'–3' exonuclease activity has been found in *E. coli*, this activity is present in other bacteria, including *B. subtilis*. In either case, elements at the 5' end of the transcript have been shown to affect mRNA stability, by affecting recruitment and activity of ribonucleases that attack there or at other sites on the RNA. The presence of the 5' triphosphate (from initiation) also reduces ribonuclease susceptibility, and removal of the triphosphate by RNA pyrophosphohydrolase (RppH) can serve as a triggering event for degradation. Modulation of transcript stability can occur by binding of factors and/or structural rearrangements that affect accessibility of the RNA to ribonucleases and/or RppH. As noted above, premature termination of transcription can determine whether the transcript includes a binding site for a ribonuclease. Translation and mRNA degradation are also intimately intertwined, as binding and processivity of a ribosome influence the susceptibility of the mRNA to ribonucleases.

Mechanisms of mRNA Degradation

In *E. coli*, the endonuclease RNase E is the major initiator of degradation of full-length transcripts that contain intrinsic terminators at their 3' ends. RNase E nucleates assembly of a complex, designated the RNA degradosome, that includes polynucleotide phosphorylase (PNPase, a 3'–5' exoribonuclease), an ATP-dependent RNA helicase (RhlB), and enolase (a metabolic enzyme that may serve as a scaffold); poly(A) polymerase is also associated with the complex. RNase E binding requires several unpaired nucleotides at the 5' end of the mRNA, and exhibits a preference for RNAs with a 5' monophosphate (generated by other cleavage reactions or by removal of the 5' triphosphate that is normally found at transcription initiation sites). Other cellular endonucleases can participate in further cleaving the RNA products, and polyadenylation, which is stimulated by endonuclease cleavage, plays a major role especially in degradation of RNAs with structural elements at the 3' end. As noted above, *B. subtilis* contains additional ribonucleases (RNase J1/J2) with 5'–3' exonucleolytic activity that may be especially important for degradation of RNAs that are protected from 3' to 5' exonucleases.

Regulation of Transcript Stability by Interactions With the mRNA Target

The crucial role of events at the 5' end of the mRNA for initiation of the degradation process provides a target for regulation by modulation of 5' end structure or accessibility. Sequences throughout the mRNA also can provide targets for endonucleases, and blocking the accessibility of these cleavage sites, through specific binding or by occupancy of the mRNA by translating ribosomes, can have major effects on the stability of the mRNA.

Regulation of mRNA degradation by RNA-binding proteins

A number of systems have been described in which binding of a protein to a transcript has a major effect on the lifetime of the transcript in the cell, and therefore on the expression of genes encoded within that transcript. This effect can be direct (by binding of the protein at a position that overlaps a site for recognition by a ribonuclease, which results in occlusion of the RNase binding site and stabilization of the transcript) or indirect (by interfering with translation initiation, thereby reducing protection of the mRNA by translating ribosomes; see below). The *E. coli* RNase E protein provides a clear example of a case where binding of a protein has been shown to directly affect mRNA stability (Fig. 6A). RNase E represses its own synthesis by binding to a complex structural

Fig. 6 Regulation of mRNA degradation. (A) Protein-dependent RNA degradation in the *E. coli rne* gene. When levels of the regulatory protein (RNase E, the product of the *rne* gene) are low, the RNA transcript is stable and efficiently translated by ribosomes (green ovals). High abundance of RNase E (pink circle) results in binding to the mRNA and increased degradation (scissors). (B) sRNA-directed mRNA degradation. In the absence of the sRNA, the target mRNA is stable and is efficiently translated. Binding of the sRNA to the mRNA by partial complementarity results in cleavage and rapid degradation of both the sRNA and its mRNA target.

element in the 5' UTR of its mRNA; this binding results in cleavage and subsequent destruction of the mRNA, and reduced RNase E synthesis. This autoregulatory mechanism takes advantage of the function of the gene product to maintain appropriate cellular levels.

RNA-binding proteins also can cause destabilization of a transcript by promoting binding of ribonucleases. An example of this type of mechanism is provided by the CsrA protein of *E. coli*, which controls a variety of carbon metabolism genes by affecting either mRNA degradation or translation initiation. CsrA binds to a helical element at the 5' end of its target mRNAs, and CsrA activity is controlled by two regulatory RNAs (CsrB and CsrC) that contain an array of CsrA binding sites and therefore titrate CsrA away from its normal targets. A second regulatory protein, CsrD, controls the abundance of the CsrB and CsrC regulatory RNAs. Binding of CsrD to the CsrB and CsrC RNAs results in their rapid degradation, mediated in part by RNase E. CsrD therefore acts as a specificity factor that directs degradation only of its designated CsrB and CsrC RNA targets. This complex system allows rapid changes in CsrA activity, and therefore in target gene expression. The related Rsm system regulates genes important for virulence in a number of pathogenic species.

RNA-mediated changes in RNA stability

As noted above, the CsrB and CsrC regulatory RNAs indirectly affect mRNA stability by controlling the availability of the CsrA regulatory protein, which in turn affects mRNA stability or translation of other transcripts. A growing number of small regulatory RNAs (sRNAs) have been identified that affect the stability of other mRNAs, without their effect being directed by a regulatory protein (Fig. 6B). These RNAs directly promote mRNA degradation (often with concomitant self-degradation) or interfere with translation initiation and therefore indirectly affect mRNA stability via the absence of translating ribosomes. Regulatory RNAs of this class (unlike CsrB and CsrC) interact with their targets by base-pairing, and may be encoded in *cis* (from the opposite strand of the same DNA region as the target) or in *trans* (from some other location in the chromosome). *cis*-Encoded regulatory RNAs are completely complementary to their targets (i.e., they are antisense RNAs), while *trans*-encoded regulatory RNAs are partially complementary and often have multiple targets within the cell. In most cases, target RNA destabilization by *cis*-encoded sRNAs requires RNase III, which cleaves long double-stranded RNA regions, while RNA degradation by *trans*-encoded sRNAs has in several cases been shown to involve RNase E. For example, the *E. coli* RyhB sRNA, which is induced in response to limitation for iron, promotes degradation of a set of mRNAs encoding proteins that bind iron, allowing more efficient utilization of limiting supplies (Fig. 6B). The activity of *trans*-encoded sRNAs (like RyhB) often depends on the RNA-binding protein Hfq, which acts as an RNA chaperone to enhance the RNA–RNA interaction, at least in part by modulating RNA folding to promote base-pairing between the two RNA partners. Both *cis*-encoded and *trans*-encoded sRNAs are usually degraded in concert with their target RNAs. Although destabilization of the target mRNA is the most common effect of sRNAs, the GadY sRNA in *E. coli*, which regulates genes involved in the response to low pH, stabilizes its mRNA targets and therefore increases expression.

Global Changes in the RNA Degradation Machinery

There is increasing evidence for modulation of degradosome composition and activity, especially in response to cellular stress. RNase E activity can be inhibited by two proteins, designated RraA and RraB, which cause alterations in the stability of many cellular mRNAs. Exposure to cold shock in *E. coli* also results in alteration of the degradosome. Starvation for amino acids activates several toxin–antitoxin systems that stimulate global degradation of ribosome-associated mRNAs, liberating resources for adaptation to the starvation state. Other general effects on translation affect overall mRNA stability via effects on ribosomal occupancy. It seems likely that a large variety of regulatory events may target RNA degradation, given the complexity of the process and its importance to the cell.

Regulation of Translation

Translation of an mRNA provides another opportunity for regulation of gene expression. In bacteria, translation can begin as soon as the RBS has appeared within the 5′ region of the transcript emerging from the transcription elongation complex. Transcription and translation are usually temporally coupled, and the efficiency with which an mRNA is recognized by the translational machinery is variable and depends on primary sequence and the presence of structural elements. Translational elongation can also be modulated by elements within the RNA or *trans*-acting factors that influence ribosome processivity. Translational efficiency can in turn affect the stability of the mRNA by affecting accessibility to endoribonucleases, as noted above.

Regulation of Translation Initiation

In bacteria, translation initiation usually involves initial binding of the 30S ribosomal subunit, initiation factors, and initiator tRNA to the RBS, which is comprised of the Shine–Dalgarno (SD) sequence (a 5-nt sequence with the consensus GGAGG that is complementary to a region at the 3′ end of 16S rRNA within the 30S subunit) and the AUG initiation codon that specifies binding of the initiator tRNA; GUG and UUG codons are also recognized, albeit at slightly lower efficiency. Translation initiation in bacteria differs from that in eukaryotic cells in that multiple translation initiation regions can be present on a single transcript, which allows the existence of polycistronic mRNAs from which multiple coding sequences can be independently translated. Binding of the translation initiation complex requires that the RBS be accessible, with no structure in the immediate region. Modulation of transcript structure in the RBS region therefore provides an opportunity for regulation that can be effective both while transcription is proceeding and after transcription has been completed.

Regulation of translation initiation by RNA-binding proteins

A number of systems have been described in which binding of a protein to the RBS region of an mRNA causes inhibition of translation initiation. As noted above, this inhibition may result not only in decreased translation of the mRNA but also in decreased mRNA stability, as a decrease in ribosome occupancy often causes more rapid degradation of the transcript. This type of mechanism is clearly illustrated in ribosomal protein genes in *E. coli*, where binding of one ribosomal protein encoded in a ribosomal protein gene operon results in sequestration of the RBS for the first gene in the operon, and decreased translation of the first coding sequence (Fig. 7A). Expression of the downstream genes in that operon is also repressed by a combination of translational and mRNA destabilization effects. Reduced translation of the downstream genes is likely to be due to translational coupling, where availability of the downstream RBS is dependent on unfolding of the mRNA by a ribosome translating the upstream coding sequence; interference with translation of the upstream region allows the transcript to fold into a structure in which the downstream RBS is sequestered. Inhibition of translation also can result in transcriptional polarity, where cryptic Rho-dependent transcription termination sites are activated by the absence of translating ribosomes that would normally occlude these sites from Rho binding. Together, these effects result in low expression of all downstream coding sequences, mediated by direct translational inhibition of only the first coding sequence.

Regulation of translation initiation by sRNAs

Accessibility of an RBS can readily be modulated by binding of a regulatory RNA, which can be encoded in *cis* (in which case the sRNA is perfectly complementary to its mRNA target) or in *trans* (in which case complementarity is usually imperfect, and Hfq protein is often used to enhance binding). Sequestration of the RBS region represents the simplest regulatory action of sRNAs, as binding of the sRNA to the RBS is sufficient to prevent ribosome binding, and recruitment of RNases by formation of a specific RNase binding site is unnecessary (although transcript destabilization is a likely indirect outcome of translational repression). There are many examples of sRNAs that repress translation, including a variety of plasmid replication control systems (which usually involve *cis*-encoded sRNAs), and the *trans*-encoded OxyS RNA, which is involved in the oxidative stress response in *E. coli* (Fig. 7B). More rarely, translation initiation can be induced by an sRNA, as is the case for induction of expression of the *rpoS* gene, which encodes the major stationary phase sigma factor in *E. coli*, by the DsrA sRNA. The *rpoS* mRNA contains a self-complementary region that encompasses the RBS, so that binding of the ribosome is blocked in the native transcript by an inhibitory helix. Binding of the DsrA sRNA to a region that includes the 5′ portion of this inhibitory helix results in unfolding of the helix, and liberation of the RBS

Fig. 7 Inhibition of translation initiation by RNA-binding proteins or sRNAs. (A) Sequestration of the SD region in *E. coli* ribosomal protein genes. When the levels of the regulatory protein are low, the SD region of the target gene (blue box) is available for binding by the ribosome (green ovals), and translation occurs. When levels of the regulatory protein are high, the protein (pink circle) binds to an RNA element that overlaps the SD region, and ribosome binding is inhibited. (B) Inhibition of translation initiation by an sRNA. In the absence of the sRNA, the SD region of the target gene (blue box) is available, which allows binding of the ribosome and translation initiation. Binding of the sRNA (green line) sequesters the SD region and prevents ribosome binding.

region so that translation initiation can occur. As noted above, effects on translation initiation also result in changes in mRNA stability, amplifying the translational effect.

Regulation of translation initiation by RNA structural rearrangements

Most of the classes of regulatory events in which RNA structural rearrangements are used to control gene expression at the level of premature termination of transcription (discussed above) can also be used to regulate at the level of translation initiation. The major difference between transcription attenuation systems and translation initiation systems is that in the latter systems the crucial regulatory helix acts to sequester the RBS of the regulated gene, rather than serving as the helix of an intrinsic terminator. For example, the processivity of the ribosome during leader peptide translation in systems like the *E. coli trp* operon determines whether a terminator or competing antiterminator helix forms in the nascent transcript, as described above. In an analogous translational control system, like that of the Gram-positive *erm* and *cat* genes (which encode resistance to erythromycin and chloramphenicol, respectively), leader peptide translation modulates whether the RBS of the downstream coding sequence is sequestered in a helix that prevents translation initiation (Fig. 1C). Expression of these genes is induced by exposure to subinhibitory concentrations of the antibiotic, which promotes stalling of the ribosome during leader peptide translation. The stalled ribosome sequesters a region of the transcript that would otherwise form an inhibitory helix that occludes the RBS of the downstream resistance gene, allowing translation of the downstream gene to commence. The stalled ribosome also stabilizes the downstream region of the mRNA, by a mechanism that may include blocking the activity of the 5'–3' exonuclease found in this group of organisms. In both the antibiotic resistance genes and systems like the *E. coli trp* operon, the translating ribosome serves as the sensor for the regulatory signal (the antibiotic or charged tRNA^{Trp}, respectively); a major difference is that transcription termination control systems like the *E. coli trp* operon require precise coupling between transcription and translation, so that the transcription elongation complex can respond to the translational signal as it reaches the termination site, while translational control systems like *erm* and *cat* can exert their effect either while transcription is taking place or after transcript synthesis is complete.

Riboswitch systems also can operate at the levels of premature transcription termination or translation initiation, and in several systems the same effector binding domain is used for both regulatory mechanisms. The major difference between transcription termination and translational riboswitch systems is the position of the final inhibitory helix, the formation of which is determined by effector binding. In transcription attenuation systems, this helix is usually located at least 30 nt upstream of the start of the regulated coding sequence, and includes a run of U residues in the transcript that together with the helix serve as the intrinsic termination signal. In contrast, the inhibitory helix in translational control systems lacks the U residues and is positioned to include the RBS (or at least the SD sequence) in the 3' side of the helix, so that helix formation occludes the RBS and prevents translation initiation. There are also examples where binding of the effector (e.g., the uncharged tRNA in T-box genes) stabilizes a helix that includes sequences that would otherwise base-pair with the SD (i.e., the “anti-SD” sequence), so that effector binding results in increased accessibility of the RBS and increased translation. In most riboswitch systems, the effector binding domain is separate

from the regulatory domain, which allows an easy transition between transcription termination control and translational control. An exception to this is the SAM-responsive S_{MK} box, which regulates SAM synthetase genes in lactic acid bacteria; in this case, the SD–ASD pairing region is an intrinsic component of the SAM-binding element (Fig. 4B).

RNA thermosensors represent the simplest class of RNA-based systems for regulation of translation initiation. In these RNAs, the RBS is sequestered into a helical structure that is stable under normal growth temperatures. An increase in temperature results in unfolding of the helical structure, and accessibility of the RBS to binding of the 30S ribosomal subunit. Regulatory elements of this type are obviously well suited to genes that are involved in cellular responses to increased temperature, and are found in certain heat shock genes including the *E. coli rpoH* gene, which encodes the heat shock sigma factor, sigma H. The *rpoH* mRNA is present in the cell during normal growth conditions, but translation is inhibited by the thermosensor element. A sudden temperature increase melts the inhibitory helix. This results in a rapid increase in sigma H protein levels, which triggers the general heat shock response by directing transcription of other heat shock genes. Restoration of the normal growth temperature allows the *rpoH* transcript to refold into the inactive helical structure, blocking further synthesis of the heat shock sigma factor and facilitating a return to steady-state conditions. Similar RNA thermosensors have been identified in heat shock genes of other bacteria, and have also been shown to regulate the *Listeria prfA* gene, which encodes a key regulator of virulence gene expression. In this case, the temperature change is used by the organism to sense movement into the host, which signals a requirement for induction of the virulence response.

Repression of translation initiation by alterations in the translational machinery

The *E. coli infC* gene, encoding translation initiation factor IF3, provides an interesting example of use of the function of a protein in an autogenous regulatory mechanism. IF3 plays a role in discrimination of authentic translational start codons. The initiation codon for *infC* itself is a highly unusual AUU codon, which is poorly recognized by initiation complexes containing IF3. Therefore, if IF3 is present in saturating amounts, translation of the *infC* gene is inhibited, and no additional IF3 is made. A reduction in IF3 abundance is signaled by the accumulation of initiation complexes that lack IF3. These defective complexes fail to discriminate against the *infC* mRNA, which results in increased IF3 synthesis until the complexes are again saturated. This regulatory mechanism is absolutely dependent on the presence of the AUU codon, which is found in *infC* genes of many bacteria, suggesting that the regulatory mechanism is conserved.

Regulation of Translation Elongation or Termination

The shift from translation initiation to elongation requires addition of the 50S ribosomal subunit, and loss of initiation factors. Once this step has occurred, the translating ribosome becomes highly processive, and is generally effective at displacing RNA structural elements or bound proteins. As noted above, translating ribosomes can affect the stability of the transcript by preventing access of ribonucleases, or the structure of the mRNA, which can affect transcription termination or translation initiation for downstream coding sequences.

Codon bias effects

Processivity of the ribosome during translation is dependent on the supply of charged tRNA entering the A site of the elongation complex. The presence of a codon for which the corresponding charged tRNA is at low abundance can cause a transient pause in translation; this is the basis for leader peptide transcription attenuation systems, as described above. Not surprisingly, codons for which the corresponding tRNAs are not abundant in a given organism are not heavily used in that organism. These rare codons can generally reduce translational efficiency, and bias against rare codons has been noted in highly expressed genes, such as those encoding ribosomal proteins. The presence of rare codons also can be used in regulation of gene expression. The best-characterized example of this is provided by the *Streptomyces coelicolor bldA* gene, which encodes a tRNA specific for the UUA leucine codon. This codon is rarely used in the *Streptomyces* genome, with a strong bias for genes involved in developmental processes. The *bldA*-encoded tRNA is dispensable for normal growth, but a *bldA* mutant is defective in secondary metabolism and sporulation because of the presence of the corresponding UUA codons in the genes required for these processes. Regulation of *bldA* expression can therefore affect a variety of genes containing UUA codons, resulting in a shift in the gene expression pattern; this effect can be further amplified if *bldA*-regulated genes include genes that encode regulatory proteins that affect expression of other groups of genes.

Programmed frameshifting

While translating ribosomes are usually resistant to structural features in the mRNA, certain RNA structural elements can promote ribosome pausing; elements of this type are important for alterations in normal coding, such as programmed frameshifting and insertion of unusual amino acids like selenocysteine. Frameshifting occurs when a ribosome shifts from its standard triplet decoding of an mRNA to a movement by 1 nt either forward (+1 frameshift) or backward (−1 frameshift). The ribosome then resumes translation, and decodes a different set of triplets on the same mRNA. Programmed frameshifting is a genetically encoded phenomenon that directs ribosomal frameshifting at a specific site, and in a specific direction. It can promote synthesis of multiple products from the same mRNA, as in the *E. coli dnaX* gene, which encodes two subunits of DNA polymerase, one of which is derived from a shift in reading frame that is dependent on both a structural element and a primary sequence element that promotes pausing of the elongating ribosome. A frameshift event is also used in autoregulation of the *E. coli prfB* gene, which encodes a translation termination factor, ribosome release factor 2 (RF2). The *prfB* gene is highly unusual in that it contains a UGA nonsense codon early in the coding sequence. Translation termination at UGA codons employs RF2, and efficient termination at this site (and failure to

synthesize additional RF2) occurs when cellular levels of RF2 are high. A decrease in RF2 abundance results in ribosome stalling at the UGA codon; this stall increases the probability of a shift of the ribosome into an alternate reading frame, which allows synthesis of the full-length RF2 protein. Like a variety of other autogenous control systems, *prfB* autoregulation makes direct use of the function of the RF2 protein in translation termination to modulate expression of its gene.

Conclusion

The variety of posttranscription initiation gene regulation events that occur in bacterial systems demonstrates the versatility of the gene expression machinery. Each step in gene expression represents a potential target for regulation, and the investigation of multiple gene systems in a broad range of experimental organisms broadens our appreciation of what remains to be discovered.

Glossary

Benthos The substrate at the bottom of the sea or fresh waters. Most benthic protozoa live in the spaces between sediment particles.

Commensal Of a protozoon – one that is loosely but not obligately associated with another organism (e.g., the ciliates attached to the external surfaces of crustacean zooplankton).

Endosymbiont An organism living in a long-term association inside a host organism for their mutual benefit (e.g., the endosymbiotic methanogenic bacteria that live inside anaerobic protozoa and utilize waste H₂ produced by the host).

Eukaryote An organism with membrane-bounded nuclei in its cells. Protozoa are unicellular eukaryotes.

Heterotrophic Mode of nutrition in which carbon is obtained from the organic compounds made by autotrophic organisms.

Phagotroph An organism that ingests solid food particles (e.g., bacteria).

Planktonic Living in the water column of lakes or the sea.

Protozoa are microscopic eukaryotic organisms. Each protozoon typically exists as a single, independent cell, and all free-living protozoa fit to the definition of phagotrophic microbial eukaryotes. In some species, independent cells unite to form colonies (e.g., colonial choanoflagellates) (Lee et al., 2000). There has never been unanimous agreement as to where the boundaries of the protozoa should lie, largely because of the extraordinary diversity of their lifestyles (Margulis et al., 1990; Finlay and Esteban, 1998; Weisse, 2017). Many species cause disease (e.g., malaria); Others thrive as commensals in the digestive tracts of ruminants and wood-eating insects, and many plant-like flagellates (e.g., *Euglena*) have at various times been referred to as protozoa, algae, or plants. Here, the authors are concerned principally with free-living protozoa, and the definition of this group is not taxonomic but one that is based on its key function in the natural environment: Protozoa are capable of phagotrophy – the ability to capture and ingest food particles (Fenchel, 1987). Many also have functional chloroplasts or endosymbiotic algae, and the resulting consortia are known as “mixotrophs” because they are capable of both phagotrophy and phototrophy (Esteban et al., 2010). Like most microorganisms, protozoa have very large population sizes, and they are the most abundant group of phagotrophic organisms in the biosphere. Biodiversity at the level of protozoa has characteristics that are not shared by macroscopic animals and plants. Most protozoan species are probably globally ubiquitous, so the global number of species is relatively small. A significant proportion of local protozoan species richness, at any moment in time, is rare or cryptic and awaiting the arrival of environmental conditions suitable for growth and reproduction.

Functional Roles

All of the important functional roles of free-living protozoa derive from their small size. The smallest flagellates are 2–4 µm and most are <20 µm, most amebae are <50 µm, and most ciliates are <200 µm. Exceptionally, some ameboid protozoa, such as the radiolarians and foraminiferans, and the agglutinated foraminiferans of the deep-sea benthos, may reach 2 mm or more, especially if they have spiny extensions. Because protozoa are so small, most suitable prey items are other, smaller microbes. Protozoa are the principal consumers of the immense natural resource of bacteria and other microorganisms, and because they have population growth rates that are similar to those of the microbes on which they feed (doubling times on the order of one to several days), they are usually able to control microbial abundance. Flagellated protozoa can probably consume all bacterial production in the plankton. In the benthos, protozoa overlap in their niche requirements with nematodes, rotifers, tardigrades, turbellarians, and gastrotrichs, but because of their great abundance protozoa are indeed quantitatively the most important grazers in the freshwater and marine (including deep-sea) benthos. Also, just as microbes achieve astronomical abundance on a global scale, so too are the protozoa that graze on them represented by species populations with proportionately smaller but still unimaginably large global abundances.

Protozoan grazing on microorganisms also stimulates activity of the whole microbial community, in both oxic and anoxic environments. The process involved is not fully understood, although it may operate by increasing the rate of turnover of essential nutrients that would otherwise remain locked up in the bacterial biomass. The net effect is that grazing by protozoa stimulates the rate of decomposition of organic matter (Fenchel, 1987, 2008; Finlay et al., 1997).
